At Ballyconnell we found two sites agreeing generally with Mr Burchell's description. In each of these the boulder-clay is excessively stony, containing hundreds of thousands of fragments of all shapes and sizes. These are broken with sharp angular fractures, especially in the lower part of the deposit: and it would not be difficult, if any one chose to spend a few hours on the unprofitable task, to collect a large number of fragments bearing a superficial resemblance to artificially formed implements. But having regard to the geological history of the area, and to the nature of the boulder-clay deposits themselves, we could not admit the possibility of any of the stones thus collected being artefacts.

In view of the serious nature of the claims made by Mr. Burchell, we feel that he should be called upon to substantiate them on the spot—preferably in the

presence of a competent jury of geologists and archæologists, selected by some neutral body. We feel also that Mr. Reid Moir should be requested to demonstrate to the same jury the possibility of manufacturing, from the material available at Rosses Point, Levallois scrapers (or any other sort of tool) by the complicated process which he describes.

Until these things have been done, we must express and maintain a complete disbelief in the authenticity

of this alleged discovery.

R. A. S. Macalister, J. Kaye Charlesworth, R. Lloyd Praeger A. W. Stelfox.

Dublin, Oct. 8.

I have to thank Mr Burchell for the generosity of his personal attitude towards the problem of the stone flakings that he has found at Rosses. I regret that I cannot accept his views, but as I am not acquainted with the site, I will refer only to the flakings themselves, judged on their own merts, which I have had good opportunities of examining.

It is not easy to describe differences of technique, nor the differences of intention, or the lack of any intention, that one senses behind the technique. It is largely the personal equation of judgment

At the moment, I will only say that I can see no suggestion of prehistoric technique in this collection of flakings, neither can I see any example of intentional secondary working. For myself, I can see no passable resemblance in any one of these flakings to any form of prehistoric implement, either palæolithic or neolithic S HAZZLEDINE WARREN

# The Habits and Economic Importance of the Rough Whelk-Tingle (Murex erinaceus).

In 1925 I reported to an oyster company that "in 1924–25 the whelk-tingle (Ocinebra (Murex) erinacea) was very abundant and very destructive. In my experiment 'A,' fully half of the brood of 1924 were found bored by the whelk-tingle, and it was obvious that most of the young oysters had been attacked in the early summer of 1925, since many of those bored had put on new growth."

The results obtained in the experiment quoted may be taken as roughly representative of what had happened in the beds. In the following year, 1926, there were strong indications that quite 50 per cent. of a good spatfall on the beds had been eaten by the whelk-tingle. Murex is fought on the beds by the dredgermen bringing in—on extra payment—clumps of spawn, as well as the living adult animal, but the rate of destruction is probably much less than the rate of increase, so that the pest is growing worse. Relief from this pest cannot, therefore, be obtained economically by oyster-producers in the present state of knowledge.

It is common knowledge, however, among experienced practical oyster-producers that the whelk-tingle—and it is interesting to record *Echnus miliaris* also—is almost annihilated on beds after a severe winter. Unless, therefore, a new method of capturing Murex can be found, those oyster-producers who are handicapped by swarms of the pest, cannot expect abatement of the damage they cause until a very hard winter is experienced.

It occurred to me that if one knew enough about the habits of Murex, it would be possible to estimate its negative economic value as an oyster-destroyer, and offset this against the increased cost of production

of oysters, i e expenditure on extra wages, incurred in its destruction. For example, if individual Murex eat on the average one brood oyster a month during nine months of the year, and brood oysters are being bought at one penny each to lay on the beds, then the negative value of a Murex at the beginning of the period of nine months is about ninepence per annum. If Murex eats on the average more or less than one oyster brood per month, its negative value will be more or less than that amount. Suppose the negative value be sixpence per annum, then a man catching Murex at the rate of 40 per day, and being paid wages at the rate of 10s. per day, would be increasing the potential value of the stock of the beds In order to obtain some information on this subject, I carried out a few experiments this year to confirm a few previous ones made in 1922 The results of these experiments show that (a) of 15 oysters bored and eaten by Murex, the average time taken was about 57 days; (b) of 10 brood oysters bored, but not eaten, the average time taken was 41 days, but if one case of 13 days be omitted, the average time works out at about 31 days; (c) of 8 brood oysters nearly bored through and abandoned, the average time taken was about 4 5 days. These latter cases were probably special ones, where the shell was too thick or the borer became too weak to complete its work. These preliminary experiments show that Murex can attack and devour an oyster brood from 1 to 2 inches long—in 5 to 6 days. In the sea, or under better conditions than are possible in a laboratory removed from the oyster beds, this period will probably be reduced by reason of the better average condition of the borer, and the probability that once the oyster is bored, and—consequently—opened in the sea, other animals will share in the teast with the borer.

I have not had the opportunity of finding out how frequently one and the same Murex attacks and destroys oysters, and suggest that this problem, as well as that of finding a new and efficient and cheap method of capture on the beds, may be advocated as a special piece of economic research. If Dr. Dodgson, at the Government Fisheries Experimental Station at Conway, is eventually successful in producing oyster spat by the million, these will have to be put out in the sea to grow, and to withstand the attacks of natural enemies. Unless, therefore, beds can be found where Murex is a negligible factor, it may be anticipated that the spat produced under artificial conditions will be destroyed in greater numbers than natural spat. The problem is thus an important one in oyster culture.

In the experiments mentioned above it was found that Murex attacks small oysters at almost any place on either the flat or convex side; the borer may sit on the oyster, or it may successfully attack it by lying on its 'back' with the prey firmly held over it by means of the foot. (See the photo reproduced in Fig. 1, for which I am indebted to Mr. A. J. Smith.) Oysters are frequently attacked and abandoned; they may be abandoned for unknown reasons when partly bored, or after a complete boring if either a chamber, or a loose horny layer (see Orton and Amirthalingam, J.M.B.A., 14, 4; 1927), is encountered; or if the oyster is in a poor or pathological condition. There is probably a limit to the depth beyond which Murex of a given size cannot use its mechanical boring apparatus, but this limit is greater than 3 millimetres. The shells of oysters rarely attain a thickness of 3 millimetres at even the age of three or four years.

In 1922 Murex attacked brood oysters throughout the period of the experiments from the end of January to the middle of March; this year similar results were obtained from July to the middle of October,

the whole period of the observations.

Murex, however, like Purpura lapillus, feeds on barnacles as well as oysters, and some individuals in my experiments have preferred to attack and eat barnacles when there were oysters in the same dishes In this year's experiments it was found that Murex attacked *Balanus perforatus*, a large species of barnacle (see Fig. 1 on the right), Balanus crenatus, and another unidentified barnacle, either by boring a hole through the shell or directly through the operculum, and the time taken to destroy B. perforatus was similar to that spent on boring and eating oysters. The smaller balanids are eaten at a much quicker rate In the sea Murex probably eats all kinds of acorn barnacles Thus barnacles, when present in abundance on oysters, a condition so frequently deplored by oyster cultivators, protect the more valuable animal by offering

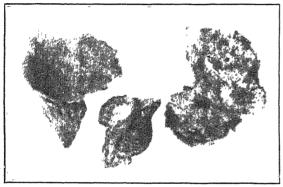

Fig. 1.—Two living Muiex boring oysters and one eating Balanus. The middle West Mersea Murex is laid on its 'hack' holding by its sucker-like toot and boning an oyster spat The left-hand Murex is also on its 'back' holding and boning an oyster brood, both are from West Mersea. The right-hand Murex, from the Fal estuary, is itself covered with small barnacles and is eating, after having bored, a Plymouth Balanus perforatus. (Photo of the living animals in sea-water by Mr A. J Smith.)

themselves as a first source of food to either Murex or Purpura lapillus, the smooth whelk-tingle. One individual of Purpura attacked and ate an oyster in my experiments, but this species clearly prefers barnacles, without confining itself, however, to either

oysters or barnacles.

Murex will also attack Crepidula, as I have found by experiment, but it is either unaware from strangeness of the value of Crepidula as food, or incapable of attacking it easily; a few bored shells of Crepidula have been picked up from oyster beds, but in these instances the borer may have been either Murex or Purpura. It might, however, be possible to introduce into the Thames Estuary oyster beds a natural borer enemy of Crepidula as a means of keeping down that pest, but it would be necessary first to discover whether that particular borer attacked oysters, i.e. O. edulis.

It is an interesting fact that Murex may return to complete its work of boring an oyster, time after time, even after it has been forcibly removed from its prey. In one case I removed an individual from its boring four times, and laid it on its 'back' each time not less than 1 cm. away from the borng, it returned to the same boring each time like a dog returning to a bone. In other cases individuals have returned to their boring after respectively two removals and one removal from both oysters and barnacles, while in some few instances the Murex has not returned after being removed. The Manoilov and other 'Chemical Sex Reactions.'

SINCE 1924, Joyet-Lavergne, working with plants and Protozoa, has been developing the view that in general female sexual cells are more reducing than male as judged by their effects on the colours of dyes; recently 2 he considers that they contain more reduced glutathione because they give the colour reactions of this substance more strongly. In 1922, Manoilov 3 developed a 'test for sex' in plants by an elaborate treatment of dyes of the rosaniline series as a result of which the female side was made to display the deeper colour, that is, the reverse of the Jovet-Lavergne effect, Satina and Demerec 4 have confirmed and developed this test, applying it to animal tissues, and amongst others to the cladoceran Crustacea Moma and Daphnia <sup>5</sup> More recently, Falk and Lorberblatt,6 working again with animals (manimalian ovary and testis), have demonstrated that the test depends on an oxidation phenomenon, the more complicated Manoilov technique being replaceable by the oxidation of colourless p-leucaniline in the presence of sufficient ferric chloride by which the temale side again produces the deeper colour of p-rosamline and is therefore apparently more oxidising than the male, Falk and Lorberblatt also report an interesting parallelism' in that the extract of testis which they used was found to have considerable reducing power as shown by Tunnicliffe's method of estimating glutathione? whilst the ovarian extract had none, and Sir Frederick Hopkins tells me that this disparity has been long familiar to him.

In 1923 (unpublished work) I myself found that the shore-crab Carcinus when inflicted with the parasite Sacculina (in which case the males are apt to assume a feminine appearance) suffered a diminution of sulphur and the nitroprusside reaction distinetive of glutathione, and have since demonstrated the same phenomenon in several ways. Although 1 have never found clear evidence of a normal sexual difference in the content of glutathione in Carcinus, it has become apparent that the assumption of feminine characters by the male goes hand-in-hand with the decrease of its nitroprusside reaction and is therefore perhaps associated with the removal of a substance of a disulphide type which may be of considerable importance in tissue exidations. On applying the Manoulov, and the Falk and Lorberblatt, and other tests of the same nature described below, I find that parasitised male crabs invariably display a relatively female reaction whether their external morphology be modified or not; at the same time it was evident from the first that glutathione is not solely responsible for the reactions, because they can be procured from the blood in which the nitroprusside test fails to indicate the presence of reduced gluta-

thione.

The dye tests for sex which I have employed on various crustacea, Cancer and Carcinus (Brachyura), Homarus, Pandalus 2 spp., and Crangon (Macrura), Gammarus (Amphipoda) in various physiological states, sexual immaturity, parasitism (by Sacculina, Portunion, or Phryxus), and hunger, as well as on the diœcious plant Mercurialis annua, may be summarised as follows:

(1) The direct action of an extract on the dye (p-rosaniline). The female side is typically the more reducing, that is, the Joyet-Lavergne effect

(2) Oxidation of the reduced dye (p - leucaniline)

P. Joyet-Lavergne, CR Ac. Sci. Paris, 179, 1212; 1924.
 P. Joyet-Lavergne, CR Ac. Sci. Paris, 184, 1088; 1927.
 E. O. Manoilov, Bull Appl Bot Plant-Breeding, 13 (2), 503; 1922.
 S. Satina and M. Demerec, Sevence (New York), 1925, p. 225.
 S. Satina, Proc. Soc. Exp. Brol. Med., 22, 466, 1925.
 K. G. Falk and I. Lorberblatt, Brit. Jour. Exp. Biol., 4, 305, 1927.
 H. E. Tunnichiffe, Bioch. J., 19, 194; 1925.

by a minimal quantity of oxidising agent (ferric chloride or hydrogen peroxide) in the presence of tissue extracts. The extracts are inhibitory to the oxidation, apparently through combining with the oxidising agent, and female extracts are typically more effective than male, i.e. the Joyet-Lavergne effect produced with the leuco-dye. This test is more obvious than the Joyet-Lavergne and more constant than the remainder.

(3) Oxidation of p-leucanilme by excess of oxidising agent in the presence of extracts. The inhibitory effect observed under (2) is now destroyed, and the female side usually presents the deeper colour of dye. Evidently there are at least two factors which set up the oxidation conditions of the extracts, and a reducing factor which is present in greater force in females is destroyed by the oxidising agent

This is the Falk and Lorberblatt test (4) Destruction of p-rosaniline by potassium permanganate in the presence of tissue extracts. Potassium permanganate enters into combination with the extractives, quantitatively more so in female extracts which may therefore be considered the more reducing, the remainder is free to destroy the dye, and does so more rapidly in the case of males probably because they remove less permanganate. It is necessary to destroy the excess of permanganate by introducing a reducing agent, sodium thiosulphate or allyl thiocarbamide (thiosinamine)—but these apparently do not themselves decolorise such dye as may be unacted upon, except on very long standing or heating.

This is the Manoilov test; it is, in general, the most brilliant of the series.

(5) Schiff's rosaniline and sulphur dioxide test for aldehydes. Minute quantities of aldehydes (which restore the colour to this colourless compound) are very rarely present in fresh extracts, and then usually in males. If the solution be heated, the colourless compound dissociates and the full colour of the dye appears, to disappear again by recombination on cooling if the whole of the sulphur-dioxide be not boiled away; in the presence of tissue extracts the same phenomenon takes place, but (typically) on the male side the colourless compound is reformed much more slowly and less readily, which may possibly indicate that a factor which is capable of combining with and so removing sulphur-dioxide is more predominant in the male sex.

The tests may be applied either to aqueous (trichloracetic acid) or alcoholic extracts, but with the exception of No. 5 they are more successful when the reaction is strongly acid; I have failed to confirm Falk and Lorberblatt's observation that the presence of protein greatly enhances the disparity between the sexes, at least in trichloracetic acid extracts. Alcoholic extracts still exhibit differences after keeping for eighteen months, but dried tissues do not keep well.

It must be clearly understood that the tests are so delicate that some noticeable difference between two extracts is almost always observed, and that equally differences can often be discovered between two samples of the same extract as a result of faults in technique; moreover, biological conditions such as nutrition and maturity themselves produce profound effects and may be compared by these tests one with another, so that the distinction between a pair of extracts which differ only in sex is occasionally not at all obvious and still more frequently is 'reversed.'

I cannot subscribe to the view that these methods are 'tests for sex'—they are tests for certain oxidising or reducing properties in the setting up of

which more than one chemical factor plays a part, although they are undoubtedly closely associated with sex and also with other biological conditions.

MICHAEL PERKINS.

#### Metallurgical Photomicrographic Apparatus.

The article on Metallurgical Photomicrographic Apparatus which appeared in Nature of Oct 8 can scarcely be considered satisfactory to those who desire to know the essential requisites of such an apparatus.

While certain engineering details are minutely discussed, scarcely any attention is paid to the essential requirements of such instruments, namely, the quality of the optical train and the methods of illumination

In photographing the extremely fine structure of metals, methods of illumination have been recently introduced which require adjustments on the apparatus which are not always provided. The method employed by Mr. Harold Wrighton in revealing structure of the order of 140,000 lines to the inch, and the new method of illumination devised by Prof. Carl Benedicks, are examples, and certain of the British instruments referred to are better equipped with these adjustments and are to be preferred.

With regard to the mechanical points which are discussed, the author, discussing the form of the optical bench, states that with the elongated triangular prism "freedom of movement and accuracy of adjustment might be obtained," and then makes the very definite statement that "it is impossible to machine the surfaces with the desired degree of accuracy to avoid shake." This is not the case if the triangular bar is machined with ordinary engineering accuracy, and the saddles bear on suitable surfaces unless the clamp is badly designed. The lathe bed type of a 'V' and a flat is an equally good design if the clamp is properly applied, as is also the parallel bar when properly constructed.

The geometric design depends for its accuracy on the accuracy of the bar, but the principle is not preserved when the apparatus has to be clamped securely in position. It must also be borne in mind that the design should be such that the apparatus can withstand wear, and to secure this sufficiently large bearing surfaces must be provided. The substitution of surfaces for points in a geometric design practically cuts out the geometric principle.

With regard to the focusing adjustments, it is difficult to see a convenient design in which both of the two focusing adjustments can be made without an overhanging weight, and as the coarse adjustment can be clamped and the fine adjustment cannot, it is much more desirable that any overhanging weight should be avoided on the fine adjustment. In a well-made fitting it does not cause any noticeable sag, but it has a marked tendency to cause 'sticking' in a fine adjustment, due to the lubricant being squeezed out from certain portions of the slide, causing metal to metal contact.

After all, there are various ways of providing convenient and efficient movements and adjustments for employing the optical equipment, all of which if properly made are satisfactory in use.

CONRAD BECK.

#### 69 Mortimer Street, W.1.

It is, of course, well known that for satisfactory work in any branch of microscopy, excellence of the optical parts of the apparatus is a prime essential.

In the article referred to, however, it was intended, as was suggested near the beginning of the article, to discuss only the mechanical construction of the various Any detailed reference to the method ınstruments of illumination, which is undoubtedly an item of considerable importance in metallurgical microscopy, was also thereby excluded When referring to items to which the user might attach importance because they suited his particular method of working, the writer had in mind the various methods of illumination employed, including the universal vertical illuminator fitted to the Beck instrument, which permits of the use of various types of transparent and of opaque reflectors which are easily interchangeable and easily adjustable in every required direction. Reference was also made in the article to the wide range of adjustment of the elements of the illuminating system provided by the British instruments These adjustments facilitate the use of the methods of illumination mentioned by Mi. Beck, but, as was suggested, the method of obtaining the adjustments might be improved.

In the production by ordinary engineering methods of the optical bench of the elongated triangular prism type, a certain manufacturing tolerance is necessary on the angle of the prism A manufacturing tolerance is necessary also on the angle of the saddle. If shake is to be avoided, no such tolerance can be permitted on either of these components. The geometrically mounted saddle will fit the triangular prism at any part of its length without shake, even though a reasonably large manufacturing tolerance has been allowed in the angle of the prism. When the saddle is in use, the forces brought to bear on it are not great; the relative movement of the saddle and the prism is not great; and the wear is thus not severe of the contact surfaces need therefore not be at all large. A properly designed clamp for the saddle should produce a pressure uniformly distributed amongst the five points. The only result of this departure from the geometric principle is to set up strains in the saddle. For effective clamping these strains need not be great, and the ordinary saddle is sufficiently robust to withstand them without perceptible deformation.

With regard to the focussing adjustments, it may be pointed out that the stage is subjected to varying loads. Frequently, fairly heavy objects are placed on it. These loads are effective on an overhanging stage whether the coarse adjustment is clamped or not.

There are, certainly, various ways in which the necessary movements and adjustments of the several parts of the photomicrographic apparatus may be obtained. The method selected should be such as is likely to be most efficient in use, and the design such as to be capable of being satisfactorily made at a reasonable cost. THE WRITER OF THE ARTICLE.

#### Science and Philosophy.

PERMIT me two comments on the references to my Huxley Lecture in the leading article in NATURE of Oct. 22.

In my judgment the writer put the cart before the horse when he suggested that philosophy had been changing the "fundamental conceptions of science." By the ordinary methods of science, prodigious advances in knowledge have recently been made, especially in mathematics and physics, and it is philosophy that is engaged in trying, in her usual

way, to bring herself up-to-date.

The writer refers to an "emergent theory" as if it had been an important principle, by overlooking which my polemic against vitalism had missed its mark." He may not agree with me, but so far from overlooking that odd theory, I described its origin

and explained how in my opinion it was a conspicuous example of the interpolation of an imaginary principle in an unfinished scientific story

P CHALMERS MITCHELL.

My intention was not to exalt philosophy at the expense of science, but to plead for co-operation between the two I cannot agree with Dr. Mitchell that the recent great advances in mathematics and physics have come about solely through the ordinary methods of science. Equally important has been the critical investigation of the fundamental concepts, for example, of time and space, which has gone on side by side with the discovery of new facts. Such criticism of concepts is generally regarded as a main function of philosophy, and if it be carried out—as it should be—by the scientific worker limiself, it remains none the less philosophy. In the sphere of biology we urgently need, it seems to me, this same combination of observation, experiment, and the critical study of fundamental conceptions

I have not accused Dr. Mitchell of overlooking the theory of emergence, and I even agree with him that in some of its forms it is regrettably vague. My point was rather that he appears to treat all forms of non-mechanistic doctrine as if they were based upon dualistic vitalism. This is obviously not true, for example, of Dr J. S. Haldane's views, or of Prof. A. N. Whitehead's 'organic' theory of nature.

The Writer of the Article.

#### An Aspect of the Biochemistry of Sugars.

In reply to Mr. Levene's letter in NATURE of Oct.

29, I would direct attention to the following points:
(1) Even if the hypothesis of inversion in the hydrolysis of sugar phosphates in Nature is correct, it may well be difficult to find the conditions for the mutation of the process in the laboratory. Mr. Levene has recently contributed a striking example in which inversion occurs with one reagent but not with another.

(2) The behaviour of glucose-3-phosphoric acid (or is it allose-3-phosphoric acid?) is highly interesting and important, but the glucose-galactose change involves position-4, where the stereochemical con-ditions are different. We know many cases—some are in the camphor group—in which direct replacement occurs as the result of steric influences, although analogies indicate that inversion should be regarded as the normal event in these reactions.

(3) The evidence that the pentose-phosphoric acid from mosic acid (Levene and Jacobs, 1911) is d-ribose-5-phosphoric acid is inconclusive, because a  $\delta$ -xylonolactone-phosphoric acid might be stable in acid solution at 40°. Admittedly the evidence favours the view of Levene and Jacobs, but it needs to be supplemented by methylation methods.

(4) Assuming that the pentose-phosphoric acid is d-ribose-5-phosphoric acid, that does not dispose of the main thesis, for the possibility exists that, in the original nucleic acid, the phosphoric acid is attached to the sugar molecule at more than one point (compare Thannhauser). Moreover, the migration of the phosphoric acid residue from one position to another in the chain is a possibility that must be kept in mind.

In short, the subject bristles with so many theoretical and experimental difficulties that it is doubtful whether a full discussion is possible at the present time.

Finally, my suggestions were not put forward as firm conclusions; I thought it worth while to advance them in order to indicate what seemed to be a useful working hypothesis. R. ROBINSON.

Sept. 29.

## Study and Research in Physics.1 By Sir Ernest Rutherford, OM, PRS

T is little more than fifty years since special laboratories began to be built, generally on a small and modest scale, for study and research in experimental physics and for the practical instruction of students. During this period, physics in Bristol has been represented by three professors, first for a short time, by the late Prof. Sylvanus Thompson, whose contributions to science will long be remembered, then by Prof. Chattock, who is held in high esteem by all his students for the efficiency and inspiration of his teaching. On his retirement he was succeeded by his pupil, Prof. Tyndall, and I am sure that it is not entirely an accident that this splendid laboratory, which we open officially to-day, had its inception and completion during his tenure of

I have always felt a certain bond of union with the University of Bristol, partly because your Council has thought fit to select as your teachers some of my friends and colleagues of other days, and partly also because I have always had a special interest in certain lines of research that have been carried on in the Physics Department. I refer to the investigations made here on the passage of electricity through gases, with special reference to the nature and life history of the charged ions which transport the electric current.

In my youthful days, when I was working as a research student in the Cavendish Laboratory in Cambridge, one of my first essays in investigation, under the guidance of Sir J. J. Thomson, was a study of the way in which a current passes through a gas which is made temporarily conducting by the action of X-rays. It was found that this weak conductivity could be ascribed to the production in the electrically neutral gas of positively and negatively charged carriers, or ions, as they were termed, which moved in opposite directions in an electric field. Information on the nature of these ions was obtained by observing the average speed of these ions when acted on by an electric field.

Although my work in later years has been in other directions, I have always retained a lively interest in this subject, and I well remember my excitement and pleasure when I read in the Philosophical Magazine for 1899 a paper by Prof. Chattock giving an account of an ingenious and powerful method for studying the mechanism of the discharge from electrified points, which is always accompanied by the long-known phenomenon of the electric wind. He was able to show definitely for the first time that the discharge was carried by a stream of charged ions, identical in character with the ions produced in the same gas by the action of X-rays. These experiments not only disclosed the mechanism of the simplest form of electric discharge, but also showed us in a convincing way that the nature of the ions

¹ Address delivered on Oct 21 in opening the Henry Herbert Wills Physics Laboratory, University of Bristol

was the same, whatever the process causing the ionisation

If time permitted, I should have liked to direct your attention to the extraordinarily interesting and varied phenomena which underlie the discharge of an electroscope by the action of X-rays or radium rays. Since 1896 this subject has been investigated by a large number of workers in all parts of the world, and no one has contributed more to our knowledge in the early days than my old friend, Prof. Langevin, whom we welcome as our guest to-day I must also particularly mention the researches in recent years on the lifehistory of an ion, the avidity with which it seizes on the molecules of water added to a dry gas, and the still greater avidity for the heavy molecules of alcohol and the consequent sluggish movements of the loaded ion. On this aspect of the almost human behaviour of the gaseous 10n, the researches of Prof Tyndall and his students have given us most valuable information

At first sight, it might well be thought that a study of the mechanism of the discharge of a gold-leaf electroscope under the influence of ionising radiations, however interesting it might prove to the scientific investigator, could be of little importance to the advance of science as a whole and of no obvious practical application. I have, however, taken this example of pure scientific research to illustrate the remarkable consequences that may sometimes follow the detailed study of an apparently trivial and smallscale phenomenon, made with no other object than to understand the processes of Nature, and I am sure in most cases with little idea of the important results that were ultimately to accrue both to science and industry

In the first place, the ionisation of a gas by radium and X-rays gave into our hands a weapon of great power and range for studying quantitatively the nature of X-rays and the rays from radioactive bodies. This has been largely mstrumental in unravelling the wonderful sequence of transformations that occur in radioactive matter, and has led to the discovery of more than thirty new unstable elements. In the second place, the information obtained of the mechanism of the passage of a current under the simplest condition could be at once applied to more complicated forms of electric discharge. It was soon recognised that the beautiful and varied phenomena which are observed when an electric discharge passes through a gas at low pressure was a consequence of the ionisation of the gas by the strong electric fields, similar, but more complicated than the discharge from a needle point. One of the first results of this study was the discovery of the electron, that mobile entity which we now know is one of the ultimate units in the structure of all atoms. Nor must we omit to mention the remarkable consequences that have followed the detailed analysis of the positively charged ions or positive rays that are always present in the discharge In the hands of Sir J J Thomson and Dr Aston, this has given us a method of precision for studying the isotopic constitution of the elements and for measuring the relative weights of the individual atoms with a certainty and an accuracy that would have appeared quite impossible a few years ago

It would take me too long to attempt to enumerate to you the great additions to knowledge that have been gained by a study of the effects of swiftly moving electrons and ions produced in a vacuum tube in exciting radiations visible and Indeed, it is true to say that a large part of the scientific advance in physics in the last thirty years may be traced as an almost direct consequence of the observations on the ionisation of a gas by X-rays I must, however, refer m passing to the great importance to science and industry of the emission of electrons from glowing bodies—a type of unipolar ionisation—that has resulted in the development of electric oscillators for radio-telegraphy of wonderful power and flexibility, and receivers for magnifying weak currents which have rendered possible the remarkable advances in wireless and broadcasting in recent years. In another direction, too, the effect of light in causing the emission of electrons from bodies—the so-called photo-electric effect—is the foundation of methods for transmitting pictures to a distance, and no doubt before long will give us television on a practical scale.

I hope I have made clear to you by this example the importance of encouraging in our laboratories fundamental research quite apart from any question of their possible application to practical ends. We live in an age when not only do many of the great industries, but also the Government, recognise the importance of the application of scientific methods for the rapid development of industry. Fortunately in Great Britain the Department of Scientific and Industrial Research is alive to the importance of fundamental research in our university laboratories, and by grants and other ways encourages the training of promising students in research method. It also in some cases assists and I hope will long continue to assist—some of our university laboratories in prosecuting important fundamental researches which are on too costly a scale to be undertaken without financial strain on the slender resources of our universities and other scientific institutions.

Since the War there has been a notable increase in the number of scientific men who are engaged either in fundamental research or in applied research with special reference to industrial problems. The question thus naturally arises as to the nature of the research work that should be carried out in a laboratory like this. Should the spare time of its teachers and research students be devoted to investigations on the fundamental problems of physics, quite apart from any question of immediate practical bearing, or to researches of a character likely to be useful in industry? This is an important question, but I should unhesitatingly say that our pure science laboratories should in the main

be set aside for fundamental research. from the interest and importance of adding to our knowledge of the processes of Nature, experience has shown that discoveries of the greatest significance to mankind, whether in the practical or intellectual sphere, are generally the outcome of fundamental research undertaken purely with the aim of adding to knowledge Industrial research should be undertaken by manufacturers or the Government in special laboratories where the research workers can come into close contact with manufacturing conditions This does not exclude the desirability of occasionally conducting applied researches in university laboratories, especially where one or more of the staff may have a special knowledge of the problems involved In general, however, I should view as an unmitigated disaster the utilisation of our university laboratories mainly

for research bearing on industry

When I look back over the thirty or more years of my connexion with research, I am conscious that I have always been looking for a breathingspace when, for a few years, no advances of consequence would be made; when I should gain an opportunity for studying in more detail, at my leisure, the ground already won. Alas, that breathing-space has never come, and I am sure will never come in my time It seems to me that the remarkable period of advance in physics, which began thirty years ago with the discovery of X-rays, shows no sign of retardation but rather of an everincreasing acceleration. It is becoming more and more difficult for the scientific man to keep in close touch with the advances in even a relatively small branch of his main subject, much less to read more than a fraction of the papers that are published in an ever-increasing stream.

This is especially the case at the present moment, when there is not only a rapid advance in experimental knowledge and technique but great activity in theoretical physics. The advent of the new or wave mechanics, with special reference to atomic problems, which promises to give an entirely new orientation to our ideas of the relation between radiation and matter, has much increased the difficulty, for the scientific man has to learn a new mathematical alphabet and language to keep 11. touch with this remarkable development, for which we owe so much to our visitor, Prof. Born of

Gottingen

While this difficulty is common to all scientific workers in a rapidly advancing subject, it is especially felt in comparatively small and isolated institutions in this country and still more in our distant Dominions. There arises, in many cases, a hopeless feeling that it is impossible to keep abreast with the flood of new scientific results and ideas, or to distinguish the wheat from the chaff. This reacts on the energy and enthusiasm of the scientific worker and diminishes the efficiency of his teaching and research.

This real danger can in part be surmounted by the co-operation and goodwill of our university authorities. If the scientific man is to maintain his intellectual activity and enthusiasm, it is in most cases important that he should be given leave of absence at regular intervals, and encouraged to visit other scientific centres, whether at home or abroad, and to get into personal contact with the workers in his special field. The value of such 'refresher' intervals is difficult to exaggerate, whether to the individual or the institution which he serves. I am sure that there are few scientific men that would not benefit by such opportunities.

At no time in the history of physics has there been a closer co-operation and sympathy between the two great branches of physics, the experimental and theoretical. With the ever-growing complexity of experimentation and technique, it is rare in these days that a scientific man can claim to be proficient in both of these branches. There has thus arisen the need that these complementary divisions should be adequately represented in a Department of Physics. I am very glad to see that this has been recognised in your University

by the appointment of Prof. Lennard-Jones as professor of theoretical physics. In addition, the institution of research fellowships to attract to the laboratory young men who have shown marked ability for research is a step in the right direction, and I hope that it will be possible in the near future to add to their number. Under such excellent conditions we may confidently anticipate that this laboratory will fulfil the wishes of the donor by developing into one of our most important centres of training and research.

The University owes much to the public spirit shown by the city of Bristol and to the wise generosity of its citizens. I am sure that all scientific men are grateful to the University and to the donor, Mr Henry Herbert Wills, whose generous benefactions have made possible the erection and endowment of this splendid laboratory dedicated to the pursuit of scientific

knowledge

## Marcelin Berthelot.1

By Prof Henry E. Armstrong, F.R S.

THE highest testimony we can give to the genius of a departed colleague is to study his work and its bearings, as in such exercise we are bound to find food for thought and gather inspiration for the future. As one of the older chemists, I would fam bear such slight witness as I may to the effect and value of Berthelot's achievements, being the more inclined to this task from having noticed, in the younger generation, a strange lack of interest in the pioneers who laid the foundations of the science they would master, now so mighty a structure—even a failure to understand the language these pioneers used. Continuity with the past is desirable, if only in order that we may understand the mental attitude of inquirers at the time they undertook their labours and be in a position to evaluate the mental development of their ideas.

Berthelot himself, who seems to have been extremely well read even at an early age, through his studies of the alchemists endeavoured to shed light upon the beginnings of chemistry and has thereby made clear the extraordinary difficulty Few to-day can appreciate his own of the task rigid attitude towards atomic weights—how it was # that he wrote C = 6 and O = 8 almost up to the last. If his intimate story could be written, it would probably be one of a mind ever striving to be scientific, yet held in the thrall of that superhuman force we term conservatism. the force by which our human society is held together and boundthe instruct of the herd-through the exercise of which we alone survive. On the other hand, it also separates us and especially from the pastas each new faith tends to antagonise the mind of its holder against an earlier form.

The rising generation has little if any understanding of the language spoken even so recently as in Berthelot's early days. There are, however, men

 $^{1}$  The English original of an 'appreciation' contributed to  $\it Chimte\,et\,Industrie$  in connexion with the centenary celebrations of Marcelin Berthelot

still alive who knew him, though not at the beginning of his career. Let us hope that these will give us of their best-the details that will enable us to follow his psychological development as a worker. For Pasteur we apparently have this information; the lessons we gain from it are invaluable. We seem to have the clearest understanding of his temperament and to be able to follow the gradual unfolding of his powers: to appreciate the masterly logic of his disposition. to see one continuous line of thought pervading all his labours, above all, his desire to serve his fellows. Berthelot offers a surprising contrast: we know so little of the man. His seems to have been a more universal genius We are in sore need of some thread of continuity to guide us through the maze of his mind.

No episode in the history of chemical science is of greater interest than that of the discovery of dephlogisticated air by Priestley and the instant appreciation of its value by Lavoisier—conveyed in the magic word 'oxygen,' a word, however, the magic of which is not heard by young ears to-day, even in France. We can, in a measure, put ourselves into Lavoisier's position—our habit of thought still being largely that which he introduced in raising chemistry from an empiric art to a philosophy We can no longer enter into the spirit of Priestley's work—we cannot even read his language with understanding. He has been commonly regarded as a pure empiric, but it is impossible to give credit to such estimate of his character. Berthelot, indeed, has questioned the truth of his representation of himself as an empiric. There are numerous passages in his works which may be interpreted as proof that behind all his inquiries there was both method and logical purpose, though maybe the purpose of intuition only. In the preface to his collected works (1790), he himself advocates philosophical studies in the following most remarkable passage:

I am sorry to have occasion to observe that natural science is very little, if at all, the object of education in this country, in which many individuals have distinguished themselves so much by their application to it. And I would observe that, if we wish to lay a good foundation for a philosophical taste and philosophical pursuits, persons should be accustomed to the sight of experiments and processes in early life. They should more especially be initiated in the theory and practice of investigation by which many of the old discoveries may be made to be really their

own-on which account they will be much more valued by them. And, in a great variety of articles, very young persons may be made so far acquainted with everything necessary to be previously known as to engage (which they will do with particular alacrity) in pursuits truly original.

Nowhere, in our schools, have we yet acted up to these recommendations: we pay faint heed to them even in our colleges.

It is my good fortune to be able to overlook the period from 1865 to the present time—an interval of more than sixty years. I still remember how greatly, at the beginning of my career, I

was fascinated by Berthelot's achievements, especially by reading his book on organic synthesis (1860). English chemists, I may say, have always been accustomed to pay close attention to the work of their French colleagues, especially that published in the Comptes rendus de l'Académie des Sciences. Not only is the concise form in which work is there presented eminently attractive but also, almost invariably, the force of genius is apparent in each communication, some new idea being stated, some advance recorded. Moreover, Berthelot compelled attention by his persistent appearance on the boards week after week. "What has he to say this week?" was the unconscious question we asked ourselves,

as each new number came to hand Some point he always made. His method had the advantage that he made his points singly, so they went home.

Myself a student under Hofmann, Frankland and Kolbe, three of the great pioneers of our science on the organic side, I was specially prepared to appreciate Berthelot's early successes in synthetic chemistry. Few to-day will realise how great was the impression he made by his production of alcohol from ethylene

MARCELIN BERTHELOT.

and water, of formic acid from carbonic oxide and soda. of acetylene from carbon and hydrogen — this last a particularly striking discovery at the time when we were beginning to specify orgame chemistry as the chemistry ofhydrocarbons and their derivatives. The barrierbetween the living world and the laboratory had indeed been broken down, in 1828, by Wohler's achievement in preparing urea from ammonia and cyanic acid, but this was a case of Berzelian metameric change, not synthesis. Berthelot went much further and fired our imagination by

showing how two and two might be put together to make four and in ways which were extraordinary in their directness and simplicity. Not only was our vision greatly extended but our ambitions also became boundless. We saw that the pass over the heights was won and that the conquest of the great kingdom beyond was a mere matter of time. We now seem able to make what we will, when once we know what we are called upon to do. No plant is safe from our imitation. The world is arrayed in laboratory products Where our forefathers used woad as a source of indigotin, we use the pure pigment, made by thousands of tons in our factories. The

purple used by emperors in the past, laboriously extracted from multitudinous shell-fish, is now a relatively inexpensive laboratory product but laugh at Nature—in fact, we can do more than she elects to do and arrogantly wear two gloves where she is content with but one, this, her prime secret, however, is her security, it seems, one for which Berthelot did not allow when he suggested that, in the future, perhaps we should live on synthetic food—an unpardonable suggestion for a man belonging to a gastronomic nation to make, a Chemists, it is true, are clear blot upon his shield cooks but the French cook is by heredity an artist and his art one to be held in reverence, not interfered with by science and spoilt—as is brewing.

Still, the example which we perforce have followed, in our mad career of wresting so much of her prerogative from Nature, is that set by Berthelot. His methods of producing alcohol and formic acid long remained in abeyance—there was no call for their application; in recent years, however, they have been developed on the large scale. That of acetylene may be ranked as the most fruitful of his discoveries Produced by the calcium carbide process, which in its essence is Berthelot's, this gas is now used not only as an illuminant but also in the form of the acetylene blowpipe, in welding and cutting steel. Acetylene is also used as the primary material in the production of acetic acid on the large scale If, to-day, though we do not despise Nature, we are tending to put her aside and make coal the uriversal raw material, the initial fault was Berthelot's; if to do so be a virtue, the credit lies equally with him.

Regarding Berthelot, as we must, as the parent of synthetic organic chemistry, we need to be clear in our definition of synthesis, in view of the too general tendency to attach loose meanings to the terms we use and of the danger we run, especially at legal hands, of our terms being misinterpreted by those who have no feeling for their use.

We do well to remember the caution given by Gerhardt in the preface to his "Introduction à l'étude de la chimie " (Montpellier, Fév. 1848):

J'ai cherché, autant que possible, à joindre, dans l'explication des phénomènes, la précision à la clarté, prenant en cela pour modèle les mathématiciens qui ne se servent jamais d'un terme sans en avoir préalablement établi le sens. Il faudra bien un jour arriver à écrire les livres de la chimie comme on écrit une géométrie ou une algèbre; c'est alors sculement que la chimie se répandra davantage dans les masses.

In the following passage Gerhardt uses synthesis as the antithesis of analysis:

Les opérations de la chimie sont de deux espèces: elle détermine les métamorphoses, soit par analyse, soit par synthèse; elle sépare de la matière toutes les parties dissemblables, ou, par un procédé inverse, elle unit ces parties entre elles; elle décompose ou elle récompose. L'activité inhérente à la matière est son moyen; le chimiste la provoque par le contact immédiat des corps hétérogènes; il la renforce ou l'affaiblit par l'intermédiaire des agents physiques, chaleur, électricité, lumière.

The word synthesis can only be given its proper

verbal meaning: that of putting together, in the fashion so perfectly set by Berthelot, by working upwards from simple to complex. To give an example, oxalic acid may be made analytically by oxidation of sugar. it may be synthesised through cyanogen, NC CN. We have reason, however, to believe that in no case are compounds formed directly merely from their atomic constituents. The production of acetylene, in fact, is a highly complex process, involving as it does not only the resolution of the diatomic hydrogen molecule but also that of the carbon complex  $C_z$ , where x is an unknown but probably very high value. The equation may be written

$$x\mathbf{H}_2 + 2\mathbf{C}_x = x\mathbf{C}_2\mathbf{H}_2.$$

In result only is the synthesis simple. If we accept Faraday's teaching, the process is still more complex, involving other factors which make the occurrence of change possible by the inclusion of the interacting materials in an electrolytic circuit. The same may be said of calcium carbide. There is good reason to believe that, in preparing this substance, by heating carbon with lime, in an electric arc, we are but producing calcium in situ and that the carbide is formed by the interaction of carbon and the metal—again under the influence of factors which together with these constitute an electrolytic circuit. The argument is equally applicable to the synthesis of alcohol from ethylene and of a formate from carbonic oxide.

The germ of Berthelot's synthetic achievements is already forecast in his first chemical essay-Action de la chaleur rouge sur l'alcool et sur l'acide acétique " (Annal. de Chimie, 33, 295; 1851). This inquiry was undertaken to ascertain what would happen if simple substances were submitted to a red-heat, as nearly all organic substances of high atomic weight gave similar products, coal-tar being an example. His experiments proved that the hydrocarbons benzene and naphthalene, phenol and various other complex compounds were equally obtainable from the simple substances and so laid the foundation of pyrogenic synthesis. In his essay he insists, in the most definite manner possible, that the synthesis of benzene, naphthalene, etc., from their elements could henceforth be regarded as a fait accompli, inasmuch as acetic acid, from which he had prepared them, had already been produced synthetically, by Kolbe, commencing with carbon bisulphide.

Berthelot, therefore, from the outset, was prepared to give a wide definition of the term synthesis and obviously interpreted it in the sense of the passage quoted above from Gerhardt, whose writings will have been known to him. Moreover, he clearly recognises that Kolbe was his forerunner. The essay is striking testimony to the early

development of his genius.

Milestones remain from which we may infer the state of knowledge at the time when his synthetic work was begun. The volume of Liebig's Annalen (81; 1852) in which Berthelot's essay is reprinted from the *Annales de Chimie* also contains Alexander Williamson's celebrated memoir on the formation of ether. In this, as is well known, the long standing dispite over the relationship of alcohol and ether was finally settled and the constitution of the two compounds made clear The student of to-day has difficulty in picturing the crudity of belief and the slight body of knowledge of his forerunner of those by no means far away times. Williamson's interpretation was a master stroke of genius but an absolute 'bolt from the blue,' taking into account the uncertainty, if not confusion, which prevailed. We know that when he undertook the inquiry, he had not in mind the problem of which, as he ultimately saw, it gave the solution I have vainly sought for a clue to his mental development up to the stage when he suddenly took so great a step forward and defined for all time the alcoholic and etheric functions The nearest approach to an explanation which may be offered is, that he was under the spell of Gerhardt's logical genius, as may be inferred from the consistent manner in which he (also his friend Kekulé) made use of 'typical' formulæ from this time onwards. The alcohol-ether problem was ripe for solution, in fact, owing to the publication of Gerhardt's advanced theoretical views.

Another article of special historical interest, in connexion with Berthelot's work, in the volume of Liebig's Annalen referred to, is a letter from Hofmann to Liebig on "The Application of Organic Chemistry to Perfumery." Hofmann prefaces his account by directing attention to Cahour's work on the oil of Gaultheria procumbens, showing it to be a compound ether. He sees proof of the influence this had upon perfumers in the appearance in our first English Exhibition (1851) of numerous fruit ethers and describes the results of his examination of various samples which he had collected as a juryman—he had found the 'pear oil' to be amylic acetate, the 'apple oil' amylic valerate, the 'pine-apple oil' ethylic butyrate, etc To-day, such synthetic materials are used not only in perfumery but also, on a huge scale, as solvents in the cellulose and varnish industries. Berthelot soon afterwards became interested in the more complex etheral salts and, in fact, began his synthetic campaign by building up fats artificially from glycerol and fatty acids, thus crowning the work of his great countryman Chevreul

The inquiry that has received more attention perhaps than any other published under his name and probably is the most esteemed is that on etherification, in which he was associated with Pean de St. Gilles. Carried out with exceptional care and finish, dealing with a fundamental problem of the highest interest, akin to that which Williamson had dealt with in his interpretation of the conditions of metallic salts in aqueous solution, the inquiry excited the widest interest and was the prototype of many similar inquiries—none the less, even now, we are not fully informed nor agreed as to the precise nature of the process.

A branch of Berthelot's work which appealed to me in my early days was that upon oil of turpentine, in which again he appeared as a pioneer. He was the first to distinguish between the oils from various sources and especially to note the distinctive differences in optical properties.

Acetylene, if not his discovery, was first characterised by him and eventually synthesised from its elements. As this is the most fundamental of all syntheses and the gas is of great technical importance, his name will always be indissolubly linked by chemists with this hydrocarbon and its direct conversion into benzene.

Persulphonic anhydride and persulphonic acid are probably to be ranked as his most important primary chemical discoveries

The most difficult chapter in Berthelot's work to appraise is the thermochemical, including that of explosive combustion Ever a fundamentalist at heart, in this, as in all his other work, he sought for primary values. Commencing in 1865, it covers a wide range. The earlier data are probably uncertain in not a few cases In this, as in most other sections of his work, he was opening up-a new field of inquiry and methods had to be devised and developed. Such work, moreover, was scarcely suited to his imaginative temperament and impetuous mode of attack. It needs not only a highly developed sense of accuracy but also a persistence and patience and a self-denial which few possess. He came into conflict with Julius Thomsen, who was making thermochemical measurement his life work; usually, in the end, they were in agreement Berthelot probably derived his interest in such work from the example set by his great countrymen Lavoisier and Laplace. He sought to generalise and so was led to formulate his well-known three principles. Ultimately he rendered a service which it is difficult to overestimate by his invention of the calorimetric bomb, one of the most powerful engines of research yet devised. Maybe the principle embodied in its use will some day be utilised in the internal combustion engine, when oil is no longer available as a cheap fuel. Hitherto it has been used chiefly in estimating the calorific value of fuels but it has also been of service in analysis.

In fact, thermochemistry seems almost to be a subject of the past. Few to-day will realise how great was the interest we took in Berthelot's and Thomsen's results as they were published. Testimony to my own interest in the subject is to be found in the article "Chemistry," which I wrote for the "Encyclopædia Britannica" (vol. 5, ed. 9), published in 1876. I then quoted characteristic thermal data for most of the elements

It is unfortunate that chemists now so rarely take thermochemical values into consideration. When this is done, interpretations which on the surface may seem plausible are often precluded. An example may be found in the enigmatic behaviour of carbonic oxide. As H. B. Dixon was the first to show, this gas in admixture with oxygen is incombustible when dried, although if the mixture be moistened it explodes, the rate of combustion being more rapid the more moisture is present up to a certain point. This behaviour has been interpreted as proof that combustion takes place through the agency of 'water' in accordance with the equation

 $CO + O\dot{H}_2 = CO_2 + H_2$ . This interpretation is precluded, however, by the fact that the heat of combustion of hydrogen to liquid water is greater than that of carbonic oxide

Wieland has shown that such an interaction apparently does take place under the influence of palladium black but he goes further having observed that traces of formic acid are present in the liquid, he argues that formic acid is the first product

$$CO + OH_2 = H_2CO_2$$

and that this is deprived of hydrogen by the action of the palladium

$$CO_2H_2 = CO_2 + H_2$$

As formic acid has a higher heat of combustion than carbonic oxide, the formation of the acid from the gas would be an endothermic process On this ground, Wieland's modified interpretation of the combustion process must equally be ruled out of order.

On thermo- and electro-chemical grounds we may go even further and premise that carbonic oxide cannot be burnt by ordinary oxygen, even when all other necessary determinative conditions are realised. On the assumption that every chemical interchange is an electrolytic process, whenever 'conducting water' is present as a necessary element in the circuit in which interchange is effected, no action should take place at any potential below that developed in the formation of water from hydrogen and oxygen. To burn carbonic oxide, it is necessary therefore to use an oxidising agent of higher potential than ordinary oxygen, the heat of combustion of carbonic oxide being below that of hydrogen. Hydrogen peroxide is such an agent This oxide is a product of the primary interaction when hydrogen is burnt

To explain the fact that a moist mixture of carbonic oxide and ordinary oxygen is explosive, we therefore need only to assume that on firing the mixture a minute quantity of water is decomposed. that the liberated hydrogen is then at once peroxidised and that the hydrogen peroxide thus produced serves to oxidise the equivalent amount of carbonic All the peculiarities in the behaviour of carbonic oxide on combustion are accounted for by

these assumptions.

The halting use hitherto made of thermochemical data is due, in no slight measure, to a suspicion that the values, in not a few cases, are of doubtful accuracy. The difficulty of interpreting the observed values is a still greater bar. These are all based upon the study of molecular interactions, often complex in character, the direct determination of atomic values being impossible. The difficulty has been in part met, in recent years, by resort to thermo-dynamical reasoning and the introduction of 'electrolytic' methods.

We are in face of this difficulty especially in the case of carbon. Julius Thomsen's numerous calculated values for carbon compounds were all based upon Favre and Silbermann's determination (1842-43) of the heat of combustion of charcoal

carbon, made at a time when the methods were but imperfectly developed.

Berthelot, with Petit, made use of his calorimetric bomb in redetermining the value of carbon in its reputed three forms. They give as the means of closely accordant determinations the 'atomic

Diamond 94,310 gram-degree Centigrade units 94,810 Graphite Charcoal 96,960

Apart from the question as to which of the forms the theoretical heats of formation of carbon compounds may properly be referred, we have yet to show that there are forms of carbon other than the diamond. Now that there is reason to suppose, in view of Sir Charles Parsons's inquiries, that diamond has never been produced artificially, the problem is raised to an acute stage. The probability is that the reported allotropes of diamond (graphite and charcoal) are hydrocarbons containing the minute proportion of hydrogen needed to prevent the carbon atoms from lapsing into the highly stable condition they present in diamond, owing to the symmetrical, uniformly tetrahedral arrangement of the atomic units. The very small difference between diamond and graphite, the relatively large difference between graphite and charcoal are both surprising We cannot accept even Berthelot and Petit's determinations as final.

A worthy monument to Berthelot's memory and genius would be an institute charged with the duty of placing beyond question all the fundamental thermal values and of extending thermochemical study in general A vast field of fruitful inquiry lies open in the hydrocarbons especially.

It is impossible to contemplate the long list of titles—about 1500—to which his name is attached without feeling that justice remains to be done to his phenomenal activity We need a studied, critical analysis of his work, in which the logic of his progress is fitly displayed. The work of poets is considered line by line: their critics seek to reconcile the miracles they have wrought in words with the peculiarities, if not deficiencies, of their moral character. The characters of statesmen, of soldiers, sailors and explorers are often discussed in considering their deeds. Little has been done to analyse the psychology of the scientific mind, to define the special features of the scientific spirit, yet even poets have foreseen that it is the spirit of the future. With most wonderful prescience Shelley has said of man:

"All things confess his strength. . . .

The lightning is his slave; heaven's utmost deep Gives up her stars and like a flock of sheep They pass before his eye, are numbered and roll on! The tempest is his steed, he strides the air And the abyss shouts from her depth laid bare, 'Heaven, hast thou secrets? Man unveils me; I have none!""

Of such order was Berthelot. We need to have the strength of the scientific mind fully unveiled: its weaknesses too, so that we may seek to combat them in the future service of the world.

## Obituary.

MR. H M. TAYLOR, F.R.S.

ENRY MARTYN TAYLOR, at the time of his death the senior on the roll of fellows of Trinity College, Cambridge, was born at Bristol on June 6, 1842, the second son of the Rev James Taylor, D D. After being educated at Wakefield Grammar School, of which his father had become headmaster, he was sent to Cambridge, being elected to a scholarship at his college. He graduated as third wrangler and was awarded the second Smith's Prize in 1865; in that year the late Lord Rayleigh was senior wrangler and first Smith's prizeman, and the well-known economist Alfred Marshall was second wrangler. In the year of his graduation, Taylor was appointed vice-principal (with H. J. Purkiss, the senior wrangler of 1864, as principal) of the newly established Royal School of Naval Architecture and Marine Engineering at South Kensington, afterwards the Royal Naval College at Greenwich. Taylor's most distinguished pupil was Sir W. H. White, later Naval Constructor; the relation, there begun, lasted until the death of the younger man in 1913.

In the last century, Cambridge men of high degrees often looked to the Bar for a career; among mathematicians, the names of Alderson, Pollock, Rigby, Stirling, Webster, Moulton, Levett, readily occur as men who made their mark. Taylor read for the Bar; and he was called by Lincoln's Inn in 1869. He does not appear to have practised, for, elected a fellow of Trinity in 1866, he returned in the year of his call as an assistant tutor of his college. The rest of his life was spent in Cambridge. He was tutor of Trinity from 1874 to 1884, the ten-year period having been established. He remained on the staff as a mathematical lecturer until 1894, thus completing the normal maximum of twenty-five years' service in the college.

The 'seventies were an active time of academic reform in Cambridge. The old Elizabethan statutes had been partially modified by the first Victorian statutes in 1858; but a comprehensive change was made by the Universities of Oxford and Cambridge Act of 1877. Under that Act, each college framed its own statutes for submission to the Privy Council. Accordingly, Trinity proceeded with that duty in a long succession of meetings: it was at one of these that the master (Dr W. H. Thompson) relieved the momentary tension by informing a distinguished very junior fellow, still living, that "we are none of us infallible, not even the youngest." When decisions had been completed, the final drafting of the statutes was entrusted to three of the fellows: Prof. Cayley, whose reputation as a draughtsman long survived his retirement from practice at the Bar: Rev. Coutts Trotter, conspicuous for his share in the organisation of the University, especially in the domain of natural science: and H. M. Taylor, whose legal training proved of high value. Then, and for many years to come, Taylor had a prominent (if not foremost) part in giving effect to the necessary changes in the old system. Independent in thought, and scrupulously just, he maintained

the even tenor of his views, devoted to progress yet mindful of the ancient ways, fair in constructive act, and straight in opposition. Those statutes are now under repeal; their actual initial working owed much to the prudent wisdom of a band of refc. mers, among whom Taylor held a not unworthy place.

From the beginning of his career, Taylor was interested in research, particularly in subjects of a geometrical character His two earliest papers date from 1866, and deal—one with interpretations of planetary formulæ (unwittingly, a return to the ancient Greek cycles), the other with inversion. Later, he wrote on the algebraic theory of envelopes and developable surfaces: and he manifested a productive interest in problems of algebraic distribution, applied to chess and to probability. Gradually, his work converged upon the theory of plane curves and of surfaces · thus he discussed the centre of an algebraic curve (1890), and cubics and quarties (1897–98). Perhaps his most important paper is one dealing with cubic surfaces and a diagram of their twenty-seven lines (Phil. Trans.,

Moreover, Taylor did much work for his friends by helpful criticism of the proof-sheets of their books in passage through the press: particular mention may be made of Rayleigh's "Theory of Sound," Lamb's "Hydrodynamics" (the latest edition of which is dedicated to Taylor), and Forsyth's "Differential Equations" and "Theory of Functions." He produced one volume of his own, the "Pitt Press Euclid": it is too extensive for a schoolbook, and now too conservative for a modern practice which sometimes tends to an anarchic freedom from proof. He also wrote the "Encyclopædia Britannica" article on Newton

When Taylor's college work came to an end, it seemed as if he would be free to proceed in the range of original work belonging to the theory of algebraic curves and surfaces But misfortune seized him at the approach of leisure. In 1894 the sight of one eye failed, through detachment of the retina; and, soon, the sight of the other eye failed also. Though he did succeed in continuing mathematical research for a time with the help of amanuenses, and indeed produced several papers after the loss of sight, so that he was elected a fellow of the Royal Society in 1898, it soon became clear that this form of activity had to be abandoned. He had found the Braille volumes a solace within their range; but the comparative lack of scientific books in Braille type stirred a new idea, the realisation of which opened a new life for him

Taylor set to work and developed the Braille alphabet; he devised amplications which rendered possible the reproduction of mathematical formulæ, figures, and diagrams, even some illustrations of books. He worked in connexion with the association which produces Braille books; but its funds could not bear the high charges necessarily entailed. So some friends, admiring Taylor's courage, collected a small fund to subsidise the association. The result was a fine success. Volume after volume was translated into Braille, text-books on geometry, algebra, come sections, trigonometry, astronomy, geology, the foundations of mathematics, metaphysics, physiology, sound, music, and mechanics—a list that is not complete—were published by the help of the fund. Every symbol on every page of every volume was stippled out by Taylor's own hand, with a cheerfulness and a patience that were amazing. His work is a real contribution to the life of the blind. Financial aid for the work, thus initiated, has been placed on a permanent basis, for his friends gathered funds which, under the name of the Embossed Scientific Books Fund, have been accepted as a trust administration by the Royal Society.

This bond of communication with the world that lives by sight gave Taylor new interests. He remained a member of the council of his college, under the new statutes, being re-elected time after time. He was made a university member of the borough council of Cambridge, served as mayor in 1900–1, and for some subsequent years was chairman of the finance committee of that council. Also he was nominated a borough magistrate, and discharged the duties with characteristic regularity and fairness.

In later years, the burden of age told; and, for nearly two years, Taylor had been practically confined to his house. Unmarried, he made a home for his mother—who, in her nineties, chaffed him when he was mayor—and for his sister who survives him. At that house, The Yews, set in the college backs, he died on Sunday, Oct. 16th last; and on the succeeding Wednesday, after a funeral service in the College Chapel, he was interred in the Huntingdon Road Cemetery.

Taylor's record, from 1894 onwards, is one of rare patience: of serene courage: and of unflinching cheerfulness under calamity, without a word of complaint. He leaves behind him the memory of a man who, for over thirty years, fought his

One fight more, The best and the last.

A. R. F.1

## DR. B. DAYDON JACKSON.

A LONG life of useful work was closed by the death in Westminster Hospital, on Oct. 12, as the result of a street accident, of Dr. B. Daydon Jackson, who since 1880 had been actively associated with the conduct of the Linnean Society.

Born on April 3, 1846, in Stockwell, then near London, Jackson was educated in private schools. Though he seems to have had no special training, he was much interested in natural history; he was one of the early members of the Quekett Microscopical Club, and in 1868 was elected a fellow of the Linnean Society. His interest in our British flora brought him into touch with the botanists at the British Museum and Kew, and his special

aptitude for bibliographical work was soon apparent. In 1876 he edited, with the addition of notes and references and a life of the author, "A Catalogue of Plants cultivated in the Garden of John Gerard, in the Years 1596-1599"; and in the following year a similar reprint and edition of William Turner's "Libellus de re herbaria novus," originally published in 1538 In 1881 the Index Society published in 1538 In 1881 the Index Society published his "Guide to the Literature of Botany"—a classified selection of botanical works, which, though nearly fifty years old, it is still worth while to consult. This was followed in 1882 by "Vegetable Technology," a contribution towards a bibliography of economic botany, also published by the Index Society. Meanwhile, in 1880 Jackson had been elected to the botanical 1880, Jackson had been elected to the botanical secretaryship of the Linnean Society, for which he worked devotedly during the rest of his life, for twenty-two years (1880-1902) as botanical secretary, and then as chief of the permanent staff, with the style of general secretary, until last year, when he retired from active participation in the conduct of the Society, though his services were retained as curator of the Linnean collections. Jackson's work for and association with the Linnean Society is so well known as to need no comment Successive generations of botanists and zoologists will gratefully remember the ready help and advice which was always at their service at the Society's rooms in Burlington House manent expression of their feeling was the presentation of Dr. Jackson's portrait to the Society on the occasion of his resignation of the secretaryship at the anniversary meeting in 1926.

Jackson's most important literary work was the "Index Kewensis"—an enumeration of the genera and species of flowering plants from the time of Linnæus to 1885, the expense for the compilation of which was contributed by Charles Darwin. The work of compilation was begun in February 1882 and the final part was published in 1895. Of the first supplement, bringing the Index up to 1895, Dr. Jackson and Dr. T. Durand, of Brussels, were the authors.

Another invaluable book of reference was the "Glossary of Botanic Terms with their Derivation and Accent," which he issued in 1900; subsequent revised editions appeared in 1905 and 1916.

The Linnean Society is the home not only of the herbarium but also of the library, manuscripts, etc., of Linnæus; an intimate knowledge of these brought Dr. Jackson into touch with workers, especially taxonomists, at home and abroad. His various publications on the Linnean collections, and his recent English edition of Prof. Fries's "Life of Linnæus," may be mentioned. So highly was this aspect of his work appreciated in Sweden that at the Linnean bicentenary celebrations at Upsala in 1907 he received special honour, including a knighthood (R.N.O.), and the Hon. Ph.D. and A.M. of the University. His last important work was the recently issued catalogue of the Society's library.

The remarkable vigour of Jackson's constitution—he had never missed a meeting of the council during his forty-seven years' continuous service,

<sup>&</sup>lt;sup>1</sup> Some passages in the foregoing are taken from the writer's obituary notice which appeared in the Times, Oct 17.

and only one general meeting—gave hope that he would for some years more be able to fulfil the light duties assigned to him as curator of the Linnean collections—It has been ordered otherwise and he has fallen, literally almost, at his post.

#### Prof. A Mair.

PROF ALEXANDER MAIR, whose death occurred on Oct 7 at the comparatively early age of fifty-seven years, had occupied the chair of philosophy at the University of Liverpool since 1910 Although he made no direct contribution to purely scientific research, he was always keenly interested in recent developments of scientific theory, and extremely appreciative of their wider philosophic implications. He was the author of the articles on "Hallucination" and "Belief" in "The Encyclopædia of Religion and Ethics," of "Philosophy and Reality" (published 1911), and of "Immanence and Transcendence," and "The Idea of Transcendent Deity," in recent volumes of the *Proceedings of the Aristotelian Society*.

Prof Mair was born in Glasgow, and pursued his studies at Edinburgh, the Sorbonne, and Marburg He exercised a marked influence both within the University and in connexion with many extra-mural educational institutions, being also the first president of the recently founded Liverpool Psychological Society and active in promoting the Liverpool Branch of the British Institute of Philosophical Studies; while his philosophy seminar was attended by a growing number of post-graduate students His intellectual ability, combined with his generous disposition and patent sincerity, gained for him a wide sphere of appreciation.

WE regret to announce the following deaths.

Rev. H. N. Hutchmson, author of "Prehistoric Man and Beast," "Extinct Monsters," and other popular books on scientific topics, on Oct. 30, aged seventy-two years.

Dr. J. R. Leeson, mayor of Twickenham and author of "Lister as I knew him," who also interested himself in several aspects of natural science, on Oct. 23, aged seventy-three years.

### News and Views.

SIR ALFRED MOND'S address on the chemical industry, read by Dr. F. A. Freeth before the Central Economic League on Oct 20, ought to receive wide publicity, for it tells the plain man in plain terms how that industry, particularly in Great Britain, stands in relation to his own daily needs, his protection, his future requirements, and, in fact, his very life. Such a pronouncement, coming as it does from the chairman of Imperial Chemical Industries, Ltd., the great merger of Brunner, Mond and Co., Ltd., Nobel Industries, Ltd., British Dyes, and the United Alkali Co., Ltd., with a total of seventy-five constituent and associated companies, cannot fail to ment the closest attention of economists and of all those interested in the different aspects of the social welfare and development of the race. An analysis of the ordinary doings of the ordinary man throughout the twenty-four hours has shown that all the objects with which he deals, and most of the food he eats, have at some time or other come within the province of chemical industry. Chemicals, in fact, form the foundation of the world's industries, and hence are to be found at the very root of Imperial security and prosperity. It is of course not only the chemist who carries the technical responsibility in these concerns; as Sir Alfred Mond remarked, good engineering can also turn an unprofitable chemical process into a profitable one, notwithstanding that the same chemical reaction has been used under comparable conditions in each case. The new fertiliser process at Billingham, for example, depends for its success on the application of extremely high gas pressures. The development of an industrial technique of high pressures not only leads to commercial success in one branch of the industry, but also opens up new avenues of research and application of immeasurable national and Imperial significance.

PROBLEMS relating to agriculture, to the ultimate dependence of the food supply on the production of

fertilisers from the atmosphere, to the new realisation of the value of systematically fertilised grassland, to the possibility of the synthetic production of vitamins, were all brought under review, and attention was directed to what may be termed the 'fuel problem.' Sir Alfred Mond views with equanimity even an exhaustion of the world's timber supplies, believing that, if necessary, chemical industry would undoubtedly come to the rescue with a substitute. More remarkable still is the movement by centralised industry in repairing the deficiencies of that local chemical works which each one of us possesses in his own body. Synthetic isulin, for example, as effective m its action as its natural counterpart, is at least a vision of the early future. In speaking of industrial peace, Sir Alfred Mond referred to the fortunate happy and friendly past of the chemical industry, and outlined the plans which had been laid within the organisation of which he is chairman, with the view of promoting personal contact, improved status, increased security, co-partnership in profits, and co-operation. In the concluding words of the address. "The achievement of industrial peace cannot be hastened merely by the desires of enthusiastic amateurs or disillusioned politicians. It can be secured only by the competence and good will of those in whose hands are placed the responsibility for industrial organisations, whether on the side of direction or on the side of labour. There is a new spirit and a new science in the management of chemical industry. That new spirit and new science is the broad avenue to industrial prosperity and industrial peace."

MR. J E. WILLIAMS, whose interesting book, "In Search of Reality," was reviewed in NATURE of June 5, 1926, writes with reference to the leading article, "Science and Philosophy," which appeared on Oct. 22, to protest against any mechanistic explanation of

evolution being accepted as firmly established criticism is directed mainly against Sir Arthur Keith's address to the British Association, in which it was stated that evolution has been accomplished "under the action of forces which can be observed and measured." Mr. Williams considers that the public have taken this statement to mean an endorsement of the mid-Victorian belief in the sufficiency of natural selection, and generally as a pronouncement in favour of a mechanistic explanation of the evolutionary process. It is, he believes, "such unwarrantable materialistic dogmatism regarding the cause of evolution which has given rise to the resentment against the whole theory so manifest in religious circles at the present time." No doubt Mr. Williams is right in his diagnosis of the cause of this resentment; we would, however, point out that the leading article which was the immediate occasion of his letter expressly advocated a reconsideration of biological conceptions, and in no way proposed as sufficient or final any mechanistic views, whether of life or of evolution.

THE movement of a mountain, Monte Arbino, 5560 feet in height, is giving rise to such anxiety in the neighbourhood of Bellinzona, three miles to the east of which it is situated and not very far from the northern end of Lago Maggiore, that the authorities of the Ticino Canton in which it lies (the Italo-Swiss frontier crossing the northern end of the lake at Brissago) have ordered the evacuation of the zone of danger. The mountain has been moving horizontally since 1888, and in 1905, when the Federal Geological Survey directed attention to it, the summit had moved eastwards more than six feet in the interval. Since then it has been moving at an increasing rate per year, until during last year, 1926 alone, it had moved a foot. It has simultaneously lowered in height to a little more than the same extent, fourteen inches in 1926 The moving mass covers 2520 square yards. The movement has now reached such proportions, and such large and numerous cracks and crevasses have developed which have widened rapidly in the last few months, that the neighbouring hills of La Monde and Chiara are ordered to be evacuated, and all building operations or the felling of trees are prohibited. On account of the movement trees on the slopes of the mountain are leaning very considerably and more and more out of the perpendicular, and from time to time large falls of earth and rocks are occurring. The Survey experts believe that the mountain will before long crash down into the valley of Arbedo, and that nothing can be done to avert the fall, which, while the town of Bellinzona is itself happily protected by a granite ridge, would overwhelm the picturesque villages and farms with their groves of chestnut trees and firs, together with a large area of forest land and valuable pasture meadows.

It was announced in the *Times* of Oct. 29 that the Nobel Prize for Physiology and Medicine for 1926 had been awarded by the Karolinska Institute, Stockholm, to Prof. Johannes Fibiger, of the University of Copenhagen, and that for 1927 to Prof. Julius Wagner von Jauregg, of the University of

Vienna. The award for 1926 has, however, already been announced (see Nature, Nov. 27, 1926, p. 778). Prof Fibiger is perhaps best known by his work on the experimental production of cancer in rats behaviour of an animal with a transplanted cancerous growth may not be the same as that of one in which a tumour spontaneously develops. Filiger succeeded in producing growths of the stomach and tongue in rats by feeding them with cockroaches infested with a small nematode worm, which may be the cause of similar tumours developing, apparently spontaneously, under natural conditions. The method has enabled material for the study of the development of cancer to be obtained under experimentally controlled conditions Prof Wagner von Jauregg is well known as the originator of the malarial treatment of general paralysis of the insane. The treatment is based on old observations that the disease is frequently benefited by prolonged suppuration or fever. The first development of these observations was the production of pyrexia by means of injections of tuberculin or typhus vaccine, but more striking improvements occurred in patients who had fortuitously developed some infection Wagner von Jauregg therefore began treating patients in 1917 by inoculation with benign tertian malaria, and the method has now been used extensively both by him and by workers in other countries. Apparently permanent remissions occur in about half the cases, and many of the remainder are considerably benefited. The patient is allowed to have about a dozen typical malarial attacks and is then cured by the administration of quinine, to which the inoculated disease readily responds If the initial remission is complete, it appears to last for several years and the future may prove it to be permanent, at any rate in certain cases.

THE earthquake of Oct 24, of which a brief notice was given in our last issue (p. 630), seeins to have originated somewhere off the Alaskan coast From the seismograph records at Oxford, Kew, and Helwan, Prof. Turner suggests that it may belong to the same focus as a much weaker earthquake on Nov. 29, 1920, or in lat. 59° N, long. 149° W This position, which is about 50 miles south of the Kenai Peninsula and 320 miles west of Yakutat Bay, agrees fairly with the estimates of the distance of the origin from the University of California (1500 miles) and Ottawa (2615 miles). The evidence, so far as it goes, is somewhat conflicting. The shock seems to have been felt most strongly in the south-east of Alaska, and but slightly in northern Alaska. The telegraph cable was broken in two places, near Wrangell and between Juneau and Skagway, that is to say, in the narrow sounds of the Alexander Archipelago. Moreover, no seawaves were recorded at Honolulu, and none have been reported from San Francisco, and these might have been expected with a submarine earthquake of this magnitude. On Sept. 3 and 10, 1899, two of the greatest of recent earthquakes occurred in Yakutat Bay. They were accompanied by the most remarkable uplifts (of so much as 47 ft. 4 in.) known to us, measured six years later by the height of dead barnacles still adhering to the rocks. The epicentral area crossed narrow sounds, and, on account of the small volume of water raised, the sea-waves, though observed on the surrounding coasts, were not perceptible at great distances. It is possible that the epicentro of the recent earthquake may have occupied a somewhat similar position among the channels of the Alexander Archipelago.

Interesting records of the Alaskan coast earthquake of Oct 24 were obtained at Kew Observatory. The direct longitudinal waves (P) arrived at 16 hr. 10 min 39 sec. G.M.T., and the direct transverse waves (S) 525 seconds later. This time interval corresponds with an epicentral distance of 7320 kilometres. First and second reflections of both P and Swere recognisable. The direct surface waves were well developed, as also were those which had travelled by the long path (that is, via the antipodes). These return waves arrived 21 hours after the P phase largest earth displacement recorded on the east-west component seismograph during the surface phase amounted to 220 microns. For the Japanese earthquake of Mar. 7, 1927, and the Chinese earthquake of May 22, 1927, maximum displacements of about 500 microns were recorded.

DURING the recent visit of the Imperial Agricultural Research Conference to Edinburgh the delegates inspected the Annual Breeding Research Department of the University, the Animal Diseases Research Association, the Royal (Dick) Vetermary College, the Plant Breeding Station, and the Board of Agriculture Seed Testing and Plant Registration Stations. On Oct. 28, the Right Hon Sir John Gilmour, Bart, Secretary of State for Scotland, received the honorary degree of LLD, and delivered his address as Lord Rector of the University to the students He emphasised the clamant need for men fitted to engage in research, and said that for these they must look to the universities. The finding of satisfactory answers to two great questions--" How can we improve production?" and "How can we secure for the product the most complete immunity from the onset of disease?" -is a matter of vital concern to the home country. The extent of the British Empire and the bewildering variety of climates and soils and of animals and plants place it in a unique position as regards opportunities for research. Peculiar importance attaches to that part of the Empire which has in the tropics, for there Nature holds out the largest promise of adding to the economic wealth of the world and thereby raising the standard of comfort for mankind in general. He urged those who have the qualifications for research to realise the new opportunities which are presenting themselves and, in weighing up the prospects of a career, not to leave out of account what may be waiting beyond the seas.

At the luncheon in honour of the Lord Rector, which followed, the Earl of Balfour referred to the great advances due to those who ardently pursued knowledge without the least idea that that knowledge was going to make any material difference either to their own fortunes or to the fortunes of the world. He pointed out the difficulty of apportioning the amount of support which ought to be given to researches which

seem on the face of them completely useless, and to others in which principles are applied to the actual A great discoverer cannot be work of the world. made, but every university ought to try to give such men the chances which will enable them to make use of their unique gifts Lord Balfour said it is not easy and is not going to be easy to find enough persons with the education and the capacity to turn discoveries to the best account, but every university must set itself to do its best. The expansion of the whole apparatus of university education is a most expensive business, and the gifts of new chairs and laboratories place pecuniary obligations on the university, so that such gifts are in themselves the leason why more money is required.

A CHADWICK Public Lecture on "Tropical Vegetation and some of its Uses to Man," was delivered by Mr. W. Hales, Curator of the Chelsea Physic Garden on Oct 27. Mr. Hales was granted leave of absence by the Trustees of the Garden for the purpose of seeing tropical vegetation under natural conditions, and described in his lecture the salient features of the native vegetation and agricultural crops seen in his visit to Ceylon, the Straits Settlements, Malaya, and Java. The work of the Royal Botanic Gardens, Peradeniya, Ceylon, was referred to, and the cultivation of tea in that country was described. At Penang, the waterfall gardens are famous for their beauty, and large numbers of rare plants have been distributed from there to other gardens. From Taipang, Malay, a tour of inspection of the mangrove swamps was made; these swamps yield a large revenue to the Government from the sale of wood. Kuala Lumpur and its agricultural station were next visited. The introduction of rubber into Malaya was alluded to, and some of the research work done on rubber growing was described. In Java, the principal crops are rice, sugar-cane, and emchona for quinme, 90 per cent, of the world's supply of this drug coming from Java. The botanic gardens of Buitenzorg contain the richest collection of plants of any garden seen by Mr Hales in the East, and as a scientific institution it ranks next to the Royal Gardens at Kew.

LECTURING on "Eugenics in the Future" at Bod ford College, University of London, on Oct. 25, Major Darwin protested against the attack on eugenic reform as materialistic. It is not materialistic to use the history of the past to supply guidance for conduct in the future. Science affords no clue to the ultimate meaning and aim of the universe- these are the problems of religion and philosophy—but a scientific study of the laws of Nature enables one to form reasonable expectations as to the result of processes affecting the mental and physical development of man. Study of evolutionary principles affords the surest guide to the betterment of the race. Eugenists are in favour of schemes for social amelioration, but are convinced that they are not enough to secure social progress. The disproportionate birthrates of the more and less valuable strains at present show that all is not well with society: decrease in racial quality may coincide with an increase in material prosperity which obscures

the underlying causes of eventual deterioration. The public is not ripe for drastic eugenic legislation, even where it is desirable, but patriotism and enlightened public opinion can help to increase the birthrate of the better stocks. Self-control on the part of those with such family taints as insanity, segregation of the mentally deficient, some form of pressure applied to persons in chronic receipt of relief who have proved unable to maintain themselves or their families, and more enlightened treatment of habitual criminals, would curtail the birthrate among the less desirable strains.

Mr. Archibald Page, president of the Institution of Electrical Engineers, gave his inaugural address on Oct. 20. As Mr. Page is the engineer and manager of the Central Electricity Board, his address was looked forward to with great interest. He pointed out that our progress would have been more rapid had it not been for the rivalry between large electrical undertakings and the overzealous display of local patriotism by the smaller municipal undertakings There is no infallible remedy for the present state of things, but methods of generating electricity must be altered. In particular, electrical stations must be interconnected by a system of high-tension lines. These lines will be supported on towers eighty feet high and sixteen square feet at the base. Their design was settled after consultation with Sir Reginald Blomfield. The conductors, the pressure between which will be 132,000 volts, will be spaced at a distance of 12 feet apart. The lines will be made of aluminium with a steel core to strengthen it mechanically. The step down transformers will vary in size from 10,000 to 75,000 kilowatts, and the voltages will be varied to suit the requirements of the distributing stations Amongst the advantages claimed for 'the grid' scheme is that it will allow of the aggregate amount of spare plant to be considerably reduced, and that it will enable 'blocks' of waste heat from blast furnaces, coke ovens, and other sources to be transformed into electricity and thus usefully employed. In his last Budget speech, the Chancellor of the Exchequer said that there were signs that the centre of gravity of industry in Great Britain is moving south. By means of the grad, power can be given to facilitate the development of industry wherever it is wanted. The new scheme, however, will not appreciably affect the cost of lighting in our big cities which have modern power stations.

PRITZEL'S Iconum Botanicarum Index, which is a list of references to illustrations of flowering plants and ferms in botanical, horticultural, and other publications, has been a standard work of reference since its completion in 1865. In 1917 the Council of the Royal Horticultural Society decided to undertake the revision and continuation of Pritzel's Index, and the work has been carried out at Kew under the editorship of Dr. Otto Stapf, late Keeper of the Herbarium, with the help of the facilities of, and material already to hand in, the Kew library. Pritzel's Index contained more than 107,000 references; the new edition, which bears the title Iconum Botanicarum Index Londinensis, will contain 450,000

references, including those in the original work, to illustrations of flowering plants, ferns, and fern allies published in botanical, horticultural, and other works and journals between the years 1753 and 1920. It is also proposed to issue periodic supplements. The Index will be as complete as it has been possible to make it by consultation of the libraries at Kew, the Natural History Museum, and elsewhere, and with the help of assistance from botanists on the continent of Europe and in America The first portion is ready for press, and a circular has been issued by the Royal Horticultural Society announcing its appearance The Oxford Press is printing the *Index*, which will have the same size and form as the Index Kewensis, the references being arranged in three columns on a quarto page, alphabetically under the genus name. It will appear in six volumes, two of which will be issued in each of the years 1928, 1929, and 1930. The subscription price is £25 Intending subscribers should apply to the secretary of the Royal Horticultural Society; it is stated that the edition will be strictly limited

ALTHOUGH the front of Faraday House Electrical Engineering College suffered considerable damage by the crane which fell in Southampton Row on the night of Oct. 28, it has been found possible to carry on the work of the College. The testing laboratories received but little damage, and the work of the Standardising department is proceeding normally.

The following have been elected office-bearers of the University of Durham Philosophical Society for the session 1927–1928:—President, The Chancellor of the University—The Earl of Durham; Hon. Sec., Dr. D. A. Allan, Hon. Treas, J. W. Bullerwell; Editor of Proceedings, Prof. G. W. Todd; Chairmen of Sections—Chemical and Physical, Prof. W. E. Curtis; Geological and Biological, Prof. J. W. Heslop Harrison; Mathematical, The Rev. F. H. Jackson; Archæological and Historical, Prof. J. W. Duff; Applied Science, Dr. J. Morrow; Philosophical, Prof. J. W. Harvey.

The third annual Norman Lockyer Lecture—established by the British Science Guild as a means of periodically directing the attention of the public to the influence of science upon human progress—will be given by The Very Rev. Dean Inge, in the Goldsmiths' Hall, Foster Lane, E.C 2 (by permission of the Goldsmiths' Company), on Monday, Nov. 21, at 4.0 p.m., the Right Hon. Sir Alfred Mond, Bart., president of the Guild, in the chair. The subject of the lecture is "Scientific Ethics." Tickets may be obtained from the secretary of the British Science Guild, 6 John Street, Adelphi, W C.2, if application is inade not later than Monday, Nov. 7.

The Institute of Physics announces the thirteenth lecture of its series, 'Physics in Industry,' which is to be given at 5 30 p.m. on Monday, Nov. 14, 1927, in the rooms of the Institution of Electrical Engineers, Savoy Place, Victoria Embankment, W.C.2. The lecturer on this occasion is Sir William Hardy, Director of Food Investigation at the Department of Scientific and Industrial Research, and his subject,

"Physics in the Food Industry." The application of physical methods to the conservation of food resources is a subject of national importance, and the lecture should be of considerable interest to a far wider public than the membership of the Institute of Physics. The Board of the Institute wishes it to be known that the lecture is open to the public, without charge. Admission is by ticket, and tickets may be obtained on application to the secretary of the Institute of Physics, 1 Lowther Gardens, Exhibition Road, London, S.W.7.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned -Two jumor assistants (engineering) for research work at the Fuel Research Station, East Greenwich Special knowledge of mechanical engineering in the case of one vacancy, and of physics and mathematics in the other case, is desnable - The Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, S.W.1 (Nov. 14). A head of the building department of the Leeds Technical College -- The

Director of Education, Education Offices, Leeds (Nov. 14). A bacteriologist at the Devonshire Hospital, Buxton-The General Superintendent and Secretary, Devonshire Hospital, Buxton (Nov. 15). A plant physiologist and a plant pathologist at the Imperial College of Tropical Agriculture, St. Augustine, Trinidad, for banana research—The Secretary, Imperial College of Tropical Agriculture, 14 Trunty Square, E.C.3 (Nov. 30). A professor of pathology and bacteriology at the Welsh National School of Medicine-The Registrar, University College, Cardiff (Dec. 1) A dairy research bacteriologist at the Research Laboratories, New Zealand-The High Commissioner for New Zealand, 415 Strand, W.C 2 (Dec. 17). A lady tracer at the Admiralty Engineering Laboratory, West Drayton, Middlesex—The Superintendent, Admiralty Engineering Laboratory, West Drayton, Middlesex. A signal inspector for the Engineering Department of the Egyptian State Railways, Telegraphs and Telephones—The Chief Inspecting Engineer, Egyptian Government, 41 Tothill Street, S.W.I.

#### Our Astronomical Column.

MAGNETIC DISTURBANCES AND SUNSPOTS.—On Oct. 22, a magnetic disturbance commenced sharply at 63h and continued until 10h on Oct. 23 with an intervening diminution between 16h and midnight. During the first phase the excursion shown by the Greenwich declination magnetograph traces was 3°, and during the second about 40'. The disturbance is worth comment on account of its being one of those instances in which it does not appear possible to ascribe a connexion between a pronounced magnetic disturbance and a particular sunspot. A small stream of spots crossed the sun's central meridian on Oct. 22-26, but in general appearance it was but one of many which are now of frequent occurrence. An examination by Mr. Evershed of spectroheliograms taken at his observatory at Ewhurst, Surrey, also failed to show any unusual solar activity (the daily record at Ewhurst, as elsewhere in Great Britain, was, however, broken by cloudy weather).

It may perhaps be noted that at the time of the commencement of the magnetic disturbance the longitude of the sun's central meridian was 282°, and that this particular longitude was the position of three very large spots seen successively on the central meridian on May 12, June 8, and July 5 respectively. At the time, attention was directed to the absence of corresponding magnetic disturbances which might reasonably have been expected in view of the size and nature of the spots (see NATURE, June 18, p. 903, and Proceedings of the Astronomical Society of the Pacific, August, p. 246).

Another instance this year of the occurrence of a magnetic 'storm' and the apparent absence of any solar activity of note was afforded on July 21-22.

THE TRANSIT OF MERCURY ON NOV. 10.—The British Isles have been favoured as regards visibility of transits of Mercury in recent years. In the period since 1861 there have been nine transits, 3 in May, 6 in November, of which only one, that of 1881, was wholly invisible here, while those of 1907, 1914 were wholly visible, the middle occurring at noon. There will be a transit on the morning of Thursday, Nov. 10, of which the end will be visible in Great Britain, the sun rising at Greenwich at 7h 8m, and internal contact at egress occurring at 8h 28m. The transit is

a nearly central one, Mercury being 2'9" south of the sun's centre at 5h 46m.

Now that accurate time can be obtained so readily by radio signals, it is well to point out that amateurs can do most useful work by carefully timing the contacts, both internal and external. Such observations have a double value. First, it was largely through observations of transits that the anomalous motion of the perihelion of Morcury was detected, which was afterwards explained by Einstein. The amount of the advance of the perihelion is not yet known with absolute precision, and more observations are desirable. Secondly, it is suspected that the unexplained irrogularities in the moon's motion are due to changes in the rate of the earth's rotation. This suggestion can best be checked by observing the other rapidly moving bodies in the solar system, of which Mercury takes the first place.

Another desirable research is to examine whether any ring of light can be discerned round the portion of the planet outside the sun's disc. Such a ring was plainly seen at the last transits of Venus, being due to sunlight refracted by the planet's atmosphere. It is known that Mercury's atmosphere must be rare, but it is desirable to test whether it has any that can be

detected.

The next three transits are in Nov. 1940 (invisible here), Nov. 1953 (beginning visible here), May 1957 (invisible here). Most of the text-books indicate a transit in May 1937. There will be a near approach, when Mercury will probably be discernible in the spectroscope, projected on the chromosphere, but no actual transit.

THE ASTROGRAPHIC CATALOGUE.—Several more volumes of this catalogue have lately been published, and the end seems to be nearly in sight. The Cape volume for -49° is the last volume but one of the zone undertaken by that Observatory. It consists of 452 pages with 180 stars on each full page. Further instalments of the Catania Catalogue have lately appeared, containing  $0^{\rm h}$  to  $3^{\rm h}$  of  $+47^{\rm o}$ , and  $3^{\rm h}$  to  $6^{\rm h}$  of  $+49^{\rm o}$ . They give right ascension and declination for every star, which is undoubtedly convenient, but was rejected by most observatories as adding too much to the labour and expense of publication.

### Research Items.

MEDICINE AND SURGERY IN ANCIENT EGYPT —In Science Progress for October, Dr. Warren R. Dawson maintains, as the result of a direct study of Egyptian medical texts, that the generally accepted accounts of Egyptian medicine consist of a series of generalisations, many of them quite erroneous and based upon incorrect readings which have been copied from book to book for the last fifty years. There are a number of medical papyri in existence, of which the best known is the Ebers. Egyptian medical knowledge was clearly based upon magic, as is shown by the use of incantations by the object of the treatment, as indicated by the form of its title in the papyrus, such as 'against,' or 'to banish,' or 'to drive out' the disease, which was evidently conceived as a possession, and by the fact that even effective remedies were used magically. Some of the remedies were deliberately made disgusting or unpalatable to the possessing spirit. Surgery, however, the recently discovered Edwin Smith papyrus, which deals with the treatment of wounds, shows to have been based upon exact and scientific knowledge. This was due to the practice of mummification which early gave the Egyptians a knowledge of comparative anatomy. The hieroglyphic signs for the organs of the body are pictures of the organs themselves, but the fact that they are animal and not human organs is evidence that the Egyptians were first acquainted with the structure of the lower animals. The practice of mummification again also gave them a knowledge of physiologythe Ebers papyrus contains several sections dealing with the heart and its functions. Although the meaning of the terminology is not always clear, owing to lexicographical difficulties, and drugs, symptoms, and diseases, all alike are obscure at times, several diseases have been identified and the mummies themselves have furnished evidence of certain pathological conditions. Generally speaking, the diseases are those which attack the fellahin to-day, -mtestinal troubles due to bad water; worms and other parasites, ophthalmia and other infections of the eyes; boils, bites, skin diseases, bilharzia infection, and mastoid disease among others.

THE BIOLOGY OF A WHEAT JOINTWORM PARASITE. -The Wheat Jointworm (Harmolita tritici) belongs to a family of chalcids which includes many plant feeders. This habit is unusual, since most members of the Chalcidoidea are parasites of other insects The Harmolita is extensively parasitised by another chalcid, Eurytoma parva, which curiously enough befongs to the same family (the Eurytomidæ) as its host. The life-history of this parasite has recently been worked out in the United States by Mr. W. J. Phillips, who contributes an interesting paper on the subject in the Journal of Agricultural Research (vol. 34, 1927, pp. 743-758). It appears that the female Eurytoma prefers to oviposit in wheat stems contaming Harmolita larvæ in their first instar. Having consumed its host, the Eurytoma then apparently proceeds to complete its development by feeding upon the plant sap. There is evidence also that, if a Eurytoma, on hatching from the egg, finds itself outside a cell containing its host, it feeds straight away on plant sap and does not seek out the Harmolita. In one instance Mr. Phillips mentions that a larva of the Eurytoma that had evidently consumed a Harmolita larva and had begun to feed on plant sap, was reared to maturity upon a fully grown larva of Harmolita. It is evident that the feeding-habits of the Eurytoma are in a plastic condition and that the insect is gradually forsaking its normal parasitic mode of life and becoming a plant-feeder.

VARIATIONS IN THE PROTEIN CONTENT OF WHEAT. -W F. Gericke (Journal of Agricultural Research, vol. 35, p. 133) brings forward some explanation as to why applications of nitrogen to land may cause either an increase or decrease in the protein content of wheat. Starting with experiments on wheat grown in nutrient solutions, he showed that in a series of plants initially supplied with a complete culture solution, but later transferred to one from which a different essential element was omitted in each case, those deprived of calcium or nitrogen alone had the protein content of the gram affected; a decrease occurred in both cases. Tests were also made with a number of different wheat varieties grown in soil, the plants either receiving no nitrogen or dressings of sodium nitrate at different stages of development. The later applications (after 90 days' growth) invariably resulted in the production of high-protein grain, whereas a dressing of nitrogen at the time of planting gave a low-protein grain, and in some cases even decreased the protein content below that of the untreated sets. These varieties of wheat also showed widely different degrees of response to the nitrogen treatment in respect to tiller formation, due to the physiological and genetical properties of the plants. Some tillered freely only after a late dressing of nitrogen, while others tillered equally well whether the intrate was supplied late or at the time of planting. The explanation suggested from the correlation of these results is that where early tillering occurs, the relatively large vegetative growth gives inception to more gram than would result from a plant tillering later and further utilises most of the available nitrogen; the low-protein content of the grain in such cases is accordingly attributed to a shortage of nitrogen at the critical period. It is, therefore, possible to produce high-protein grain by supplying nitrogen to the soil during the later growth stages or by curtailing excessive grain production. Further, such experiments emphasise the fact that the properties of different wheat varieties may have an important bearing on the efficiency of any fertiliser treat-

AMPULLARIDÆ OF JAMAICA AND CUBA.—Dr. H. A. Pilsbry publishes a revision of the Ampullaridæ of Jamaica and Cuba (Proc. Acad. Nat. Sci. Philad., vol. 79). Though the members of this family present in the Greater Antilles are not rare and have been known for a long time, the literature relating to them has remained in confusion. The author uses "the generic term Ampullaria in connexion with these species because being customary it will be generally understood." This departure from orthodox methods in a systematic treatise is the more regrettable when made by one who has a world-wide reputation for systematic work and elsewhere has employed the more correct name of Pila, though he misattributes it to Roding, the editor, and not the author of Bolten's Catalogue. Dr. Pilsbry is unable to separate, as others have done, the commonest one of the Cuban forms from the Ampullaria paludosa, Say, of Florida and Georgia, and has had to change the name in the case of another species.

NEW FOSSII. PRIMATES FROM INDIA.—In Palæontologia Indica (vol. 4, new series), Dr. Pılgrım has published an account of a fragment of a palate of a new species of the important genus Sivapithecus (S. himalayensis). The paper also describes other primate material, there being further new species of Sivapithecus, of Palæopithecus; and two new genera;

Hylopithecus, of which only a single tooth is preserved, and Pondaungia, the true affinities of which are still in doubt. The author also discusses the evolution of the Anthropoidea in view of this new material and with reference to criticism of his already published views.

PRIMITIVE ARTIODACTYLA —Miss Pearson has given an account (Trans. Roy. Soc., B, vol. 215, 429) of the skulls of early Tertiary Stude and other primitive Artiodactyla, paying particular attention to the structure of the otic region. This interesting work is the outcome of a tour round most of the important university and public collections of Europe endeavour to disentangle the relationships of the primitive artiodactyls by an examination of the structure of the dentition alone results in great confusion Miss Pearson, wisely confining herself to an intensive study of the basicranial and otic regions as likely to be more conservative in their evolution than teeth, has made a survey of every specimen well enough preserved for the purpose of this investigation. Although such material is none too common, results of undoubted value and interest have emerged It can be shown, for example, that, although the North American Percherus and the European Palæocherus of the same period are at first sight so similar, the former is a primitive peccary and the latter a primitive true pig Cebochærus is suggested as being close to the ancestral line of the hippopotamus, and light is thrown on the position of other early artiodactyl genera. The paper is well illustrated with more than fifty line drawings, and is a valuable contribution to the study of extinct mammals.

RADIUM D, E, AND F -A number of track photographs obtained by S. Kikuchi with a Wilson expansion apparatus, which are described in the Japanese Journal of Physics (vol. 4, p. 143), throw some light on the mode of disintegration of these elements. source used was a silk fibre, which had been activated by contact with the surface of an old emanation tube, and was stretched across the cloud chamber. In addition to the  $\alpha$ -trails of radium F, two distinct sets of  $\beta$ -trails were found to be present, the long group being attributed to radium E, and the short group to radium D. Within the limits of the probability fluctuations, the total numbers of a-trails and of fast β-trails which appeared on 80 plates were equal, thus confirming an earlier result that radium E emits one  $\beta$ -particle on disintegration. No pairs of tracks were found which could be regarded as those of rays emitted from the same atom. It is suggested that the primary rays of radium D leave the atom with too little energy to be recorded, and that its  $\beta$ -radiation which has been observed is all of secondary origin.

Specific Heats.—The well-known technical method of heating by bombardment with cathodo rays has been applied quantitatively by H. Klinkhardt to the measurement of specific heats (Annalen der Physik, vol. 84, p. 167). A specimen of the substance to be my estigated is supported on quartz in an evacuated enclosure, and brought to any desired temperature between 100° C. and 1000° C. in an electric oven. It is then made the anode for an electron discharge at a few hundred volts from an oxide coated filament, and its subsequent change in temperature is followed by means of an embedded thermo-junction. The rate of supply of energy is known from the current and voltage, due allowance being made for contact differences of potential, and after applying the usual calorimetric corrections, the final results are claimed to be correct to within 2 per cent. Insulators and liquids

can be studied inside a hollow metal electrode. Measurements of the specific heats and of latent heats of change of phase are recorded for ammonium chloride and for a number of metals and alloys, and particular interest attaches to the behaviour of iron and nickel at their Curie points, where the specific heat was found not to fall abruptly to a value characteristic of the unmagnetised material, but merely to pass continuously and reversibly through a sharp maximum.

THE PROTECTION OF ALUMINIUM AND ITS ALLOYS AGAINST CORROSION.—A paper by H. Sutton and A J. Sidery, read before the Institute of Metals on Sept 8, contains a full account of the process of anodic oxidation of aluminium devised by Bengough and Stuart Sutton and Willstrop, by volatilising the metal in a stream of dry hydrogen chloride, have shown that the film produced consists of a coating of aluminium oxide of the order of 1 µ thick Especially when a grease such as lanoline is afterwards applied, the anodic oxidation affords an excellent means of protecting the metal and its alloys from sea-water corrosion As a result of the great 'throwing power' of the anodic process, samples of irregular shape can be satisfactorily treated without special arrangements. Parts in contact with other metals, however, cannot be treated, and the process must be used prior to the assemblage. Further, there may at times be difficulties as a result of the insulating properties of the film where good electrical contact is required. Electrolytic coatings of zinc and cadmium 0.0005 in. thick afford good protection to the metal and its alloys with the exception of cadmium on aluminium itself. Nickel coatings of the same thickness, however, were found not to give adequate protection.

CATALYST POISONING IN THE OXIDATION OF METHYL-ALCOHOL. The Chemiker-Zeitung of Oct. 12 contains an account of some investigations into the eauses of catalyst poisoning in the oxidation of methyl-alcohol to formaldehyde. Since poisoning has been found to be due to a considerable extent to impurities in the air supply, it is advisable to draw pure air from an area quite outside the range of factory products. The cost of the necessary installation is rapidly counterbalanced by the increased yield, which under good conditions has been found to amount to 92 per cent, of the theoretical value and to be easily maintained at that figure.

AN OXIDE OF FLUORINE.—No compound of fluorine and oxygon has hitherto been described, and hence the communication by Messrs. P. Lebeau and A. Damiens m the Comptes rendus of the Paris Academy of Sciences for Oct. 3, demonstrating the existence of such a compound, will arouse considerable interest. In the preparation of fluorine by the electrolysis of acid potassium fluoride, it was noticed that at the commencement of the operation some substance other than fluorine was present, and the cause of this was traced to the presence in the liquid of a small quantity of water. The new gas has not been obtained pure, but only in admixture with oxygen. From the density of the mixture and the chemical reactions, the formula of the gas has been established as F<sub>2</sub>O, and it is noteworthy that it is more stable towards a rise of temperature than the corresponding chlorine compound, Cl<sub>2</sub>O, since it remains unaltered when heated to 125° C. in contact with glass. It can also be kept unchanged for several days m contact with water and glass. With alkalies it forms fluorides, setting free oxygen; free iodine is produced by interaction with potassium iodide.

## Across Canada with Princeton.

The Princeton 'Summer School of Geology and Natural Resources,' led and organised by Prof. R. M. Field, has completed its second annual excursion. We started from Princeton on July 15 and returned on Aug 24. Meanwhile, we traversed and retraversed the North American continent by routes that very seldom intersected. Except for two nights on the steamer between Vancouver and Victoria, we slept on the Pullman that bears the arms of the School. This car has been specially constructed with kitchen, shower-bath, lecture-lantern, screen, etc. Most of our travelling was done at night, to leave the days free for geology. Of twenty-five main halts, one at Bellefonte introduced us to the Pennsylvanian Appalachians and another to the southern side of the Niagara gorge, the rest were in Canada. Last year's trip was wholly in the United States. Next year's is planned for intensive study of the Appalachians. For 1929, there is talk of a motor-car raid upon Scotland and Switzerland.

This Summer School is interesting as typical of modern America. In Europe it would be unthinkable In America, at the present time, if a project is original, striking, and 'worth while,' it can be achieved British readers will grasp the scope of the Princeton organisation when they find the Director of the Geological Survey of Great Britain among the eighteen members of Council. Of the others, two are Canadian, while a third of the total are acknowledged leaders in

the world of transport.

Obviously, the success of the undertaking depends equally upon transport and guidance. Railway facilities were supplemented by motor-cars and occasionally by steamers; and it is characteristic of the lavish hospitality of the land that the motorcars were in many cases supplied by well-wishers whose names even we cannot hope to remember. The indispensable guides were arranged for by the Director of the Geological Survey of Canada, by the Universities of Toronto, Winnipeg, Vancouver, and Harvard, and by various mining companies and private individuals. Our debt to them is fundamental, and it is proper to pay tribute to the glorious freedom of discussion which was extended to us wherever we went.

Two important motifs have actuated Prof. Field in bringing this wonderful Summer School into existence. He wished to arrange for an annual international congress of comparative geology and to have it itended by young and old together. It is part of the constitution that every year a citizen of the British Commonwealth and another from the outside world shall be invited as guests. On the present occasion, I had the great good fortune of accompanying my old friend, Prof. L. W. Collet, of Geneva, across the Atlantic to learn far more than we had even dared to hope. The party, all told, was twenty-seven men, ranging from professors to undergraduates. The interest of the latter was strengthened by the thought of an examination at the end of the course, and from their questions we others learnt many a lesson.

Perhaps, as British 'observer,' I may be permitted to record some of the impressions of the trip. In the first place, the North American Continent is, broadly speaking, a magnified mirror image of much of Europe. North America has three major divisions: (1) an Atlantic border of Palæozoic mountains (Appalachian System); (2) an immense central region (Laurentia of Suess) that has suffered no mountain-making deformation since the dawn

of the Cambrian; and (3) a Pacific Cordillera (Rocky Mountains, etc.) characterised by Mesozoic and Tertiary compression Both the Atlantic and Pacific mountains have been folded and thrust over the maigins of the intervening stable element. The latter is seldom spoken of as Laurentia, but its main pre-Cambrian exposure is familiarly styled the Canadian Shield, while its Cambrian and later systems are for the most part included in the Great Plains If now we turn to Europe, we find: (1) a Palæozoic border chain that runs through Scandinavia and Britam; (2) a central region that we may christen Baltica, a region of Cambrian and post-Cambrian tranquility, and (3) a Mesozoic-Tertiary cordillera (Carpathians, Crimea, Caucasus). Here again the mountain elements (1) and (3) are folded and thrust upon the margins of the buffer state (2) in the latter we find a Baltic Shield to match the Canadian Shield, and a Russian Platform, extending through Denmark into East Anglia, to serve as counterpart of the Great Plains of North America.

The pivot of our comparison is furnished by the mountain chain of Scandinavia. This chain is markedly symmetrical. On one side, in Sweden, it is carried forward along the Tornebohm thrust-zone on to undisturbed early Palæozoic rocks of Baltica. On the other side, as exposed in the north-west Highlands, it has travelled along the Moine thrust-zone on to undisturbed early Palæozoic rocks recognised by Suess as part of Laurentia. Across the Atlantic, the Scotto-Scandinavian mountains reappear in Newfoundland and Nova Scotia, and the Moine thrust-zone is represented by the well-known dislocation-belt of St. Lawrence and Lake

Champlain

Beyond this point the reader must proceed warily. It is only a part of the Appalachian System that corresponds with the Scotto-Scandinavian chain The Appalachian System is a complex of two of the important mountain systems of Europe. In fact, the geology of the Atlantic States of North America is summarised in the words: Where mountains cross.

Let us join Marcel Bertrand's pupils and define for tectonic purposes Calcdonian as meaning early Palæozoic, Hercynian as late Palæozoic, and Alpine as Mesozoic and Tertiary. Bertrand, after reading Dana in 1887, recognised part of the Canadian and New England Mountains of the Appalachian System as Caledonian, while he separated the Pennsylvanian Appalachians as Hercynian. The data have been greatly clarified of recent years, and the progress of knowledge as presented by authors like Clark (1921), Collins (1924), and Young (1926) has immensely strengthened Bertrand's comparisons with Europe. Young's account is particularly explicit. "Before the close of the Devonian period," he says, speaking of the eastern mountains of Canada, their strata "were folded and faulted, and invaded by granite batholiths" (Geol. and Econ. Mins. Can., p. 89; 1926). In Pennsylvania, of course, the folding is post-Carboniferous.

Many thoughts spring to the mind of the European geologist who finds himself standing in Pennsylvania on Hercynian mountains outside the line of the type

Caledonian chain.

(1) The westward convergence of the two Palæozoic chains—so far apart in Poland and Lapland, already in contact in South Wales and Ireland—has led to their actual crossing in the United States.

(2) Not only have the mountains crossed, but also the stratigraphy. In Pennsylvania there is an immense concordant succession from Cambrian to Carboniferous. In the anticlines we find our Durness Limestone (Beekmantown) as if we still stood in the north-west Highlands of Scotland. In the synclines we discover Upper Carboniferous Coal Measures (Pennsylvanian) derived from the waste of a growing Hereynian chain, and our thoughts are transferred at once to South Wales, the Ruhr, and Poland.

(3) In much of the Canadian part of the Appalachian System, a lunestone facies within the Lower Carboniferous serves as a punctuation mark between Caledonian and Hercynian movements, just as it does in the British Islos and in Belgium.

(4) It is as if the Atlantic did not exist or, in other words, as if Wegener, after all, were a true prophet.

and Potsdam sandstones (Upper Cambrian), in a post-Potsdam sandstone near Ottawa (Lower Ordovician), in the St. Peters and Winnipeg sandstones (Middle Ordovician), and in the basal Trenton limestone at Montmorency Falls, Quebec (also Middle Ordovician). There is a sufficiently close analogy between all this and the chalk and desert-sand association of the Franco-British Cretaceous (Geol. Mag., p. 102; 1924). The Cambrian to Middle Ordovician deposits of Laurentia may be interpreted as having accumulated in a warm shallow sea that bathed the shores of a low desert continent. The same facies extends into the Pennsylvanian Appalachians, where the carbonate rocks may reach as much as 8000 ft. in thickness. It is called the

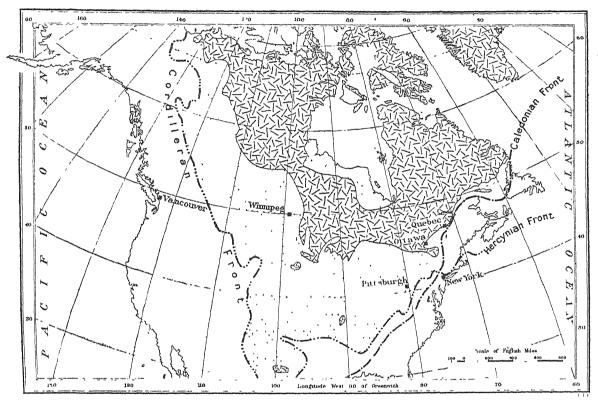

FIG 1—Tectome map of North America. The interior region (Laurentia of Suess) has remained unaffected by mountain tolding since pre-Cambrian times. Its pre-Cambrian outcrops are shown by strokes, its Gambrian and later by stipple. Modified after M. Bertrand (1887), Bailey Willis and G. W. Stose (1911), E. Blackwelder (1912), W. H. Collins (1924), G. A. Young (1926)

The thrust-zone of St. Lawrence has been mentioned as a continuation of the Moine thrust-zone of the north-west Highlands. Its interest is intensified by the fact that the thrusts have involved a transport of facies comparable with that so famous in the Alps. This last point is clearly set out in Raymond's guide for the 1913 International. Collet and I were able to add details here and there, simplifying the mapped course of certain thrusts, complicating others by recognition of successive slices—but this has only increased the charm of the story.

According to plan, the excursion maintained frequent contact with Ordovician rocks so far east as Winnipeg. The Cambrian to Middle Ordovician facies of Laurentia differs profoundly from that of the Caledonian Atlantic border. In the former district, one finds a wealth of pure carbonate rocks (marine limestones and dolomites), and there is little contamination except for wind-rounded sand. Such sand is represented, for example, in the Croixian

American facies; and in our own country it has long been recognised as characteristic of the Durness succession of the north-west Highlands.

The Caledonian facies is, on the other hand, commonly spoken of as Atlantic, British, or European. It consists of muds and sands, washed down by rivers from the ram-swept heights of the growing Caledonian chain. Its fossils are graptolites, and other creatures, including species familiar in Wales, southern Scotland, and Scandinavia

Conglomerates or breceias, varying in age from Cambrian to Middle Ordovician, are frequent in Canada and the northern States along the frontal part of the Caledonian chain. They are often interbedded among shales of British facies, but their boulders are mostly limestones of American facies. These boulders are fossiliferous; and while many of them are about the same age as the associated shales, others are distinctly older—for example, Cambrian boulders frequently occur in breceias

interbedded among Ordovician shales. The matrix, too, of every breccia that we examined near Quebec contains quartz sand that is absent from the accompanying shales. Altogether, there can be no doubt that these breccias have been correctly determined as sedimentary deposits Exceptionally, a bed of breecia contains, or at any rate accompanies, a mass of lunestone so large that the tendency has been to interpret it as a relic of a bed still in situ. One such limestone mass, in a quarry near Lévis, opposite Quebec, measures 60 ft. in length and 30 ft. in height. Collet and I returned to this exposure after the excursion was over. We satisfied ourselves that the mass had ploughed into the underlying shales and splattered them through the accompanying breccia. We felt that we were looking at a sub-marine landship that had travelled down a steep slope subject to earthquakes; and standing there we thought of Schardt and of his interpretation of the blocs exotiques of the Alpine Tertiary. The comparison, however, must not be pushed too far, since at Lévis the boulders are of foreland rather than of mountain facies. It is extremely interesting that one has to travel hundreds of miles to match the material of these boulders at the outcrop It seems necessary to accept Raymond's suggestion that their source is hidden under overthrusts.

Space forbids more than a mention of our visit to Niagara, to the vent agglomerates associated with the peridotites of Quebec, to the Pleistocene inter-glacial beds near Toronto, to the pre-Cambrian glacial beds at Cobalt, to the flat pre-Cambrian of Port Arthur and Fort William on Lake Superior, to the Keewatin and other folded pre-Cambrian forma-tions of the same region, Ramy Lake and Porcupine, to the late Glacial lakes that drained to the Mississippi and New York while ice blocked escape to Hudson Bay and the St Lawrence, to the Tuner Oil Field on the first anticline of the foothills of the Rockies. In the Rockies themselves, thanks to our guides, Kindle, Mackay, and Raymond, we saw thrust after thrust in the districts of Jasper and Banff. We also examined, near Walcott's famous fossil quarry above Field, a spectacular example of secondary doloinitisation In a cliff face, showing horizontal bedding, an abrupt wavy line runs nearly vertical for several hundreds of feet and separates black limestone from pale buff dolomite. As the bedding goes through the line without any change, it is clear that the dolomitisation has been affected by circulating magnesian solutions. I can only suggest that the portion which has remained limestone was, at the critical time, charged with oil.

of the metrior Plateaux of the Cordillera we saw gramte intruded into folded Tertiary tuffs at Copper Creek, Lake Kamloops—so far as we know, a new observation. At Vancouver we were shown the

great post-Jurassic granodiorite of the Coast Range, with late Eocene conglomerates and sands overlying its weathered top. In Victoria we were particularly interested in a complicated thrust-zone that brings (?) Carboniferous slates over Eocene pillow lavas.

A few words must be added regarding Sudbury, Ontario. Here an elliptical annular outcrop of plutonic igneous rocks surrounds an exposure of the pre-Cambrian White Water Series of sediments, an exposure that measures no less than 34 miles in length and 11 miles in breadth. The igneous girdle varies from 1 to 4 miles in width. The outside country consists of a pre-White Water complex. According to the orthodox reading, the igneous rocks of Sudbury were intruded flatly as a sill along the unconformable bottom of the White Water Series, and then the whole was bent into a basin. Knight, however, in 1917, pointed out that a sill of such extent would surely show transgressive relations. Since no trace of the White Water Series has been found anywhere along the outer boundary of the Sudbury intrusion, Knight interprets this sedimentary series as preserved within a cauldron-subsidence and the intrusive girdle as a ring-dyke. He was delighted to hear that similar phenomena on a smaller scale have been fully established in both Scotland and Norway during the last twenty years — It is scarcely necessary to point out that those who accept Knight's interpretation must dispense with the particular gravitational differentiation hypotheses that have grown out of the sill conception of Sudbury structure. These hypotheses have been much criticised on quite other grounds.

The advantage of international comparisons was further illustrated by the recognition of 'finity crush-rock' at Harvard, and by Tanton's demonstration to us of Grout's principle (Bull. Geol. Soc. Am., 36, fig. 5, p. 358; 1925) for elucidating the order of deposition of folded strata. This rather elusive principle was independently employed in an isolated case in the Scottish Highlands in 1913, but there now seems hope of its fairly frequent application—in which case extremely important discoveries are certain to result.

The account given is unrepresentative, in that it has not touched upon economic problems. This is merely due to consideration of space. The gold of Porcupine and Hedley, the silver of Cobalt, the nickel of Sudbury, the asbestos and chromite of Black Lake, the coal of Brule, and the oil of Turner Valley were all examined with the greatest interest, and time was found at Port Arthur, Iroquois Falls, and Vancouver to watch timber ground into pulp or sliced into planks. For a Britisher, it was certainly an inspiring sight to see the new 4000 ft shaft in the Porcupine gold field entirely equipped with English machinery.

E. B. Balley.

#### The Storage of Fruit.

I T is estimated that in 1924 the value of the fruit and vegetables consumed in Great Britain approximated to £100,000,000, imported fruit accounting for nearly half of this figure. The importance of this industry, with its especial hability to wastage of the products dealt with, is sufficient justification for researches into the factors which affect the keeping qualities of fruit and vegetables, apart from the purely scientific interest of such investigations. In its Report for the years 1925 and 1926 the Food Investigation Board describes the results of a number

 $^1$  Department of Scientific and Industrial Research. Report of the Food Investigation Board for the years 1925, 1926  $\,$  Pp vi+80+2 plates (London II M. Stationery Office, 1927)  $\,$  2s. 6d. net.

of researches into the various factors favouring or preventing deterioration of fruit on storage, the work including both chemical studies of apples and pears of different types during ripening and storage as well as investigations into the suitability of various kinds of store.

In the case of apples, and the conclusion is presumably applicable to similar types of fruit, it has been found that the best keeping varieties contain the least nitrogen and the most sugar, and exhibit the lowest respiratory activity. The inference is that the life-expectation of gathered fruit depends upon the amount of living protoplasm it contains and upon the extent of the accumulated sugar

reserves · death ensues when the sugar available for combustion is exhausted, and this occurs the earlier the larger the amount of protoplasm present ing with Bramley's Seedling apples from three different soils, F. Kidd and C West have shown that the nature of the soil has a marked influence on the nitrogen content of the fruit, and hence on its keeping quality In general, specimens from silt soil survive much longer than those from fen or gravel soil, at storage temperatures of both 1° C and 8° C At about the latter temperature it was found possible to double the storage life by storing in an atmosphere of 9.2 per cent. carbon dioxide and 11.8 per cent oxygen instead of in air The apples from the silt soil have a low nitrogen content but a high sucrose content, those from fenland a high nitrogen and a low sucrose content, whilst those from gravel have a low content of both constituents: their keeping qualities agree with the inference given above that the life of an apple depends on the demands the living protoplasm makes upon the sugar stores The latter and the acid present in the fruit appear to be the sole source of respirable material. Death of the fruit stored at 1° C is accompanied by a browning of the flesh, a condition known as 'internal breakdown'. in its early stages, its respiration is increased whilst the acidity decreases rapidly; but in the final stage all respiration ceases. Stored at 8° C., wastage is caused by disease, 'fungal rot,' and not by internal breakdown.

The chemical changes occurring in fruit on storage are not exactly the same in different types: thus although the respiratory processes of pears as well as apples depend on the sucrose and acid content, yet the softening occurring on ripening and storage, due to breakdown of the cell-wall and loss of pectin, is much more rapid in pears stored at 12° C, and 4° C, although at 1° C. the process is less retarded in the apple (A. M. Emmott). Caution must then be exercised in applying the knowledge obtained from experments on one type of fruit to another optimum storage conditions will vary slightly from fruit to fruit and even from one type of the same fruit to another, although certain general principles will doubtless hold good in the majority of cases. This is well exemplified by an investigation of the same authors into the efficiency of different types of store, in which they found that variety plays an important part in the determination of optimum storage conditions. Thus the Newton Wonder, which is very resistant to internal breakdown, has a longer storage life the lower the temperature, at any rate to 30° F., whilst the King Pippin, very susceptible to this form of deterioration, stores best at 40° F. When the storage life is ended by 'superficial scald,' and not by 'internal breakdown,' wrapping the fruit in oiled paper wrappers has a marked effect in prolonging it.

The problems of storage as affecting ships have been investigated by A. J. M. Smith. The chief difficulty is to obtain an efficient equalisation of temperature throughout the fruit, even when air is forced through the cargo. The simplest plan appears to be to apply the refrigeration at the top of the cargo, which is so arranged as to have vertical air spaces between the cases of fruit: in this way the distance to be travelled by the cold air is minimised and full advantage taken of its gravitational tendency to

move downwards.

This brief account gives an insight into the type of work carried out by the Food Investigation Board. The ultimate result of these and similar researches is clearly to improve the food supply of a nation which relies for the major part on food products brought from overseas.

## The Centenary of Berthelot.

MARCELLIN BERTHELOT was born in Paris on Oct. 25, 1827, and the centenary of his birth was celebrated by a series of sumptuous functions and by the inauguration of an enterprise which is to form a permanent memorial to one of the most eminent of the French chemists. For some time past committees have been in course of formation throughout France and in some sixty foreign countries for the collection of the funds required for carrying out a scheme for erecting and endowing in Paris a Maison de la Chimic associated with the name of Berthelot, the sum of about sixteen million francs has been thus collected and, during last week, some six hundred foreign delegates assembled in Paris to take part in the celebration of the centenary.

The proceedings began with a reception at the Sorbonne on the evening of Sunday, Oct 23, by M Charléty, the rector of the University of Paris. On Monday morning, in the presence of representatives of the French Government, a museum of apparatus and manuscripts relating to Berthelot was opened at the Faculty of Pharmacy by Prof. Radet; the visitors were next received at the Collège de France by M. Croizet; after speeches by the president of the German Chemical Society, Prof. Schlenk, and Prof. Bogert, of Columbia University. Berthelot's former laboratories and apparatus were inspected. Later, a memorial tablet was unveiled on the wall of Berthelot's early residence, 113 Rue Saint Martin, and speeches were made by M. Boujou, Préfet de la

Seine.

The chief meeting was held in the large amphitheatre of the Sorbonne on the evening of Oct 24; discourses were pronounced by Prof. Ch. Moureu on the work of Beithelot, and by Prof. Lacroix, secretary of the Academy of Sciences; M. Georges Lecomte,

director of the Académie française; M. Gley, president of the Academy of Medicine, M. Wéry, president of the Academy of Agriculture; M. Hodza, Minister of Education for Czechoslovakia; and by M. Paul Pamleyé. Addresses were presented on behalf of numerous academic bodies, it is indicative of the widespread interest in the celebration that the first

addresses handed in were those from Abyssinia and Alghanistan.  $\,$ 

A commemoration ceremony took place at the Pauthéon on Tuesday morning, Oct. 25, when speeches were made by M Raymond Poincaré, and by M. Galhardo, Minister of Foreign Affairs of the Argentine Republic. This was followed by a lunch in the Galérie des Batailles at Versailles, which was attended by some 1200 guests, and discourses were delivered by M. Herriot, Minister of Education; Prof. Amé Pietet, of the University of Geneva, and M. Lunatcharsky, Minister of Education to the Union of Socialist Soviet Republics.

On Wednesday morning, Oct. 26, the foundationstone of the new House of Chemistry was laid in the Place d'Iéna by M. Herriot; M. Donat-Agache, president of the French Society of Chemical Industry; M. Zumeta, the Venezuelan Minister; and Prof. Ernst Cohen, of Utrecht, spoke, and the party adjourned for lunch to the Château belonging to the French Academy at Chantilly, where discourses were pronounced by M. Leconte, director of the French Academy, and Prof. H. E. Armstrong. In the evening the delegates were received by the President of the Republic, M. Gaston Doumergue, at the Palais de l'Elysée.

It is proposed to issue a commemorative volume giving a full account of the proceedings of the Borthelot centenary celebrations. W. J. P.

## University and Educational Intelligence.

Cambridge - -Dr. Ernest Clarke has been elected to an honorary fellowship at Downing College. Mr V. B. Wigglesworth, Gonville and Caius College, has been awarded the Raymond Horton-Smith Prize for a thesis, "Studies on Ketosis: with special Reference to the Relation between Alkalosis and Ketosis" Proxime accessit, Dr. A. E. Roche, Magdalene College, with a thesis on "Pyelography, its History, Technique, Uses, and Dangers." D. Barber, Trinity College, has been awarded the Adam Smith Prize for an essay on "The International Aspect of Wages" Miss A. McC. Bidder, Newnham College, has been nominated to the University table at the Zoological station at Naples for three months from Feb. 15, 1928.

The managers of the Arnold Gerstenberg studentship in philosophy have issued an interesting list from which candidates may select an essay subject: they are, "The ultimate data of physics, philosophical aspects of the theory of relativity, the philosophical bearings of the quantum theory, technical explanation and the problems of biology, heredity, and memory, Gestalt-psychology, and the logical basis of induction."

N. Feather, H. J. J. Braddick, and N. A. de Bruyne

N. Feather, H. J. J. Braddick, and N. A. de Bruyne have been elected to Coutts Trotter studentships at Trinity College.

OXFORD —Sir Archibald Garrod has tendered his resignation of the office of Regius professor of medicine as from Dec. 31 next. Sir Archibald succeeded Sir William Osler in 1920.

The Burdett-Courts Scholarship for geology has been awarded to Mr. Partick Murray Threipland, of Christ Church.

Mr. John Mason has been elected to a Fereday fellowship at St. John's College, under the obligation of pursuing a special course of research in natural science. Mr. Mason has been engaged in research work on chemical bacteriology under Dr. Ashley Cooper at Birmingham.

A research followship in natural science and a lectureship in chemistry are being offered at Exeter College. The elections will be made on Dec 12.

The following appointments have been made at the London School of Hygiene and Tropical Medicine: Mr. Reginald Lovell, research assistant in comparative pathology. Mrs. M. M. Smith, demonstrator in bacteriology, Miss H. M. Woods, assistant lecturer in epidemiology and vital statistics.

The following free public lectures have been arranged for by the Armourers and Brasiers' Company: "X-rays and Metals," by Dr. G. Shearer, at the Royal School of Mines, at 5.15 on Nov. 8, 15, and 22, "The Deformation of Metals," by Prof C. H. Desch, at the Chelsea Polytechnic, at 8 on Nov. 30, Dec 7 and 14.

Mr. George Fletcher, who since 1904 has been assistant secretary of the Technical Instruction Branch of the Department of Education, Dublin, has just retired from that post. He has rendered valuable service to educational science throughout his career, and takes with him the best wishes of many friends both in England and in Ireland.

The North of Scotland College of Agriculture announces in its prospectus for 1927–28 university degree courses in agriculture, national diploma courses in agriculture and in dairying, a special farmers' course (one winter), and a planters' certificate course (two winters and one summer). The last-mentioned is designed as a preparation for service on estates in tropical and sub-tropical countries. Research is being carried on by mombers of the college staff in soils and dramage and in bee diseases.

## Calendar of Discovery and Invention.

November 7, 1631 —The first observed transit of Mercury took place on Nov. 7, 1631—It had been predicted by Kepler and was observed at Paris by Gassendi, who admitted the solar light into a dark chamber through a small aperture in a window

November 7, 1857.—In a letter of this date, Helmholtz, writing to the oculist Graefe, described the ophthalmoscope Of the discovery Lummer wrote "He wondered at the glare of the cat's eyes in the darkness, and studied this curious phenomenon until he learned how the light enters the eyes and is returned from the retina in such a way that it may be observed. Thus he became the inventor of the ophthalmoscope... and thus all our technical industries profit by the original research of investigators who are not inspired by dreams of wealth, but who must think and work in order to satisfy their inquiring natures."

November 8, 1887.—The invention of the gramophone was due to Emile Berliner and was patented by him on Nov. 8, 1887. The essential difference between the gramophone and phonograph is that in the former the engraving tool vibrates from side to side, while in the phonograph Edison employed the 'hill and dale' method. Berliner was born in Hanover in 1857, but emigrated to the United States in 1870 and played a conspicuous part in the development of the telephone.

November 8, 1907.—The art of telegraphing pictures with the aid of selenium cells was developed by Prof Korn, of Berlin, in 1904, and on Nov 8, 1907, he transmitted photographs electrically between Paris and London.

November 10, 1619.—Descartes in 1617, at the age of twenty-one, joined the army of Prince Maurice of Orange, and the following year, at the commencement of the Thirty Years' Wai, volunteered for service in the Army of Bavaria. However, he continued his mathematical studies and was afterwards accustomed to date the first ideas of his new philosophy and of his analytical geometry from three dreams which he experienced on the night of Nov. 10, 1619, when bivouacked at Neuberg on the Danube. He regarded this as the critical day of his life, and one which determined his whole future.

November 10, 1845.—Leverner's investigations leading to the discovery of Neptune were contained in three memoirs communicated to the Paris Academy of Sciences on Nov. 10, 1845, June 1, 1846, and Aug. 31, 1846, respectively. In the first he proved the inadequacy of all known disturbances to account for the vagaries of Uranus; in the second he demonstrated that the observed effects must be due to an exterior planet; and in the third he assigned the orbit of the disturbing body, and announced its visibility as an object with a sensible disc about as bright as a star of the eighth magnitude

November 11, 1572.—It was on Nov. 11, 1572, that Tycho Brahe discovered in Cassiopeia a new star of great brilliance. At first refusing to believe his own eyes, he got others to confirm what he saw, and continued to observe the star until the end of January 1573. He made accurate observations of its distance from the nine principal stars in Cassiopeia, and proved that it had no measurable parallax. His researches on this object were the occasion of his first appearance as an author.

November 12, 1906.—Three years after the Wright brothers had flown in America, success was achieved in Europe by the Brazilian, Santos Diumont, who first flew on Aug. 22, 1906, and also on Nov. 12, 1906, at Bagatelle, travelled a distance of 100 metres.

E. C. S.

## Societies and Academies.

#### EDINBURGH.

Royal Physical Society, Oct. 17 – J. Stephenson Eastern adepts and Western science —A. C. Chaudhuri A study on the pigmentation of the Himalayan rabbit. By controlling the temperature of the environment, Himalayan rabbits can be made to grow pigmented hair in place of white. Low temperature probably stimulates the epithelial cells of the follicles to secrete an oxidase which in combination with a chronogen produces the pigment granules — P. McIsaac Blood serum calcium and parturition in the rabbit. Seven to ten days before parturition in the rabbit there is a fall in the serum calcium content, and one day before parturition there is a further and sudden fall to a minimum. After parturition the calcium content is restored to normality, but on the numeteenth day or thereabouts of the lactation period there is a second sudden fall.

#### MANCHESTER.

Literary and Philosophical Society, Oct. 4.—E. J. Williams. The number of Compton recoil electrons. Comparison of the observed values of the ratio  $N_r/N_p$ , where  $N_r$  and  $N_p$  are the numbers of 'Compton' electrons and the photo-electrons respectively, with the corresponding observed values of the ratio  $\sigma_m/\tau$  where  $\sigma_m$  and  $\tau$  are the coefficients of 'modified' scattering and photoelectric absorption respectively, shows that to within a few per cent. (which can be due to experimental error) the theoretical assumption of a one-to-one correspondence between the 'Compton' electrons and the modified scattered quanta is valid —at least statistically. It we assume the absolute validity of this assumption,  $\tau N_r/N_p$  and  $\sigma_m$  are identical quantities, and the values of  $\tau N_r/N_p$  can be regarded as experimental values of  $\sigma_m$ . A. J. Bradley and C. H. Gregory. The structure of certain ternary alloys. Copper and zinc form five different kinds of alloy, known respectively as the  $a, \beta, \gamma, \epsilon$ , and  $\eta$  phases; the  $\alpha$  phase has a face-centred structure like copper,  $\beta\text{-brass}$  is body-centred cubic,  $\gamma\text{-brass}$ has a remarkably complex cubic structure. It consists essentially of four atom types A, B, C, D, combined in proportions corresponding to the formula  $A_2$   $B_2$   $C_3$   $D_6$ . On the whole, B and C atoms are copper atoms, A and D atoms zinc, but the atoms are not completely sorted out, and there is usually a surplus of zinc atoms. In view of the similarity between the  $\gamma$  phase of copper-zmc and the  $\gamma$  phase of copper-aluminium it was decided to test the possibility of forming mixed crystals of the two phases Alloys corresponding to the formulæ Cu<sub>5</sub> Zn<sub>5</sub> and Cu<sub>5</sub> Al<sub>4</sub> were made up and were then melted together in different proportions. Three such alloys were thus made up, and the structures in each case were identical with the structures of the binary alloys; the alloys were quite homogeneous in character The similarity between these different structures is independent of the chemical composition but is closely related to the electron distribution is in each case the same ratio of valency electrons to atoms, namely, 21:13.

#### Paris.

Academy of Sciences, Sept. 26.—A Lacroix and F. Delhaye. The existence of nephelime syemies in Rutshuru region (Central Africa).—G Urbain and Pulin Bihari Sarkar. The analogies of scandium with the elements of the rare earths and with the trivalent elements of the iron family. The resemblances between scandium and the rare earths are

mainly analytical; even from this restricted point of view, scandium most resembles thorium, in spite of the difference in the valencies. The study of the acetylacetonates, the complex fluorides and thioevanates all show the close relations between scandium and the trivalent metals of the iron group —Jacques Chokhate: Mechanical quadratures and the zeros of Tchebycheff in an infinite interval. - Henry de Laszlo: The absorption of the ultra-violet rays by the ten isomers of dichlornaphthalene. The positions and intensities of the absorption bands of the ten dichlornaphthalenes are given in tabular form—E Bruet. The upper Phocene of the Aujon valley—F. Bordas and A Desfemmes The distribution and transport of chlorides in the atmosphere. From analyses of ram water at places at different distances from the sea, it is concluded that the atmosphere may carry m suspension quantities of chlorides which, carried down by rain, represent a fall of 8.41 grams of sodium chloride per square metre. These chlorides may be carried much greater distances inland than has been admitted hitherto .- J. Dumont: The influence of prolonged cultivation without manure on the nitrogenous richness of the soil: A continuation of the work of P. P. Dehéram. The mtrogen losses found, which are in agreement with the earlier results of Dehéram, are small and can be rendered insignificant by the periodic cultivation of a leguminous crop -Pierre P Grassé and Mile Odette Tuzet: The chromatic rod and the head of spermatozoids - Raymond-Hamet: The influence of yohimbine on the intestinal action of adrenaline and of ouabaine -L. Barthe and E Dufilho: The estimation of chlorine and of sodium in the milks of some mainmalian females. In human milk, and also in that from marcs, the chloring found does not correspond with the sodium directly determined, calculation of the sodium from the chlorine gives altogether erroneous results. The chlorine varies with the period of lactation and reaches a minimum value on about the sixteenth day. Sodium is present in negligible quantity up to the forty-fifth day, and hence is probably not required by the newly-born, -Swigel and Theodore Posternak: The nucleus containing phosphorus of ovovitelline. A quantitative analysis of the products of hydrolysis of  $\beta$ -ovotyrine is given, including phosphoric acid, pyruvic acid, ammonia, arginine, Instiduce, lysine, and t-serin, the amount of the lastnamed being 28 per cent. of the original material.-Kohn-Abrest: Atmospheric diffusion of the smoke of Paris. Samples of air were taken simultaneously on the Eiffel Tower at heights 0, 57, 115, and 288 metres above the ground. The results of the determinations of carbon monoxide and dioxide are given. The purity of the air does not increase with the height, as might have been expected. - Jules Amar: The parasitic origin of cancer. The facts summarised by the author all support the parasite theory of cancer.—F Dienert and P Etrillard: The action of free chlorine upon micro-organisms. Determinations of the amounts of free chlorine per litre required to sterilise nine species of organisms. The proportions required vary from 0.1 mgm, per litre to 8 mgm, per litre. The results appear to be best explained by the chemical theory of Barker.

## Technical Education and Industry.

EPEATEDLY in these columns we have urged a revision of traditional philosophies of education We have shown that, as a result of the transition from a non-scientific to a scientific basis of civilisation, vast powers have been placed in man's hands—powers by which life can be freed from unnecessary toil, and denuded of the harmful mysticisms, superstitions, and pruderies which cramp its social, political, and ethical qualities. Far from making recommendations which would tend to a system of education built merely upon an arid, mechanical efficiency, we have insisted that a knowledge of the truth of the natural world as shown through physics, chemistry, astronomy, and like subjects, and a knowledge of the truth of man's place and relationships in the scale of life as shown through subjects such as biology, is not incompatible with, but the sound basis of, an appreciation of beauty whether enshrined in literature, art, or an ordered state which understands race experience sufficiently to be able consciously to control its future experience

So much for what might be called fundamentals They may be regarded by an instinctively (and, in some respects, rightly) conservative academia as involving changes too sweeping to be practised until the present machinery of civilisation can absorb them. We agree that there may be something in the objection. We realise that the vast body of new knowledge which science has produced during the last twenty years or so and thrust into practical use in social, industrial, and commercial fields has not yet been grasped by legislators, teachers, and business men We cannot avoid noticing, for example, the unconscious legal cruelty which may arise from failure to discern the dividing lines between the scopes of law, medicine, and sociology. Nor can we fail to observe how great issues which will shape the future are constantly fogged or misdirected by ignorance. The vast forces of science have not yet been co-ordinated and absorbed by the dominating operators of our social mechanism so that the community may reap the benefit But although it is clear that, in spite of a recent suggestion, it is impossible to call a temporary halt in the world of science, we can sympathise with the view that its discoveries and implications must be more widely understood if order is to be brought out of the present chaos.

Obviously, the production of that order will be a slow progress: obviously, it must depend upon a system of education carefully planned with the view of a better social order. These are facts which must be faced steadily. But a carefully planned system of education will not, in itself, solve our difficulties. The welfare of Great Britain and its institutions rests ultimately on the success of its industry. That is another incontrovertible fact. Teachers have been reminded of it frequently, but it must be faced equally by those responsible for the successful development of industry itself.

For the benefit of the mind careful to the point of fearfulness, we would point out that, in urging a revision of educational notions, we have not presented suggestions which have been unduly hurried Those suggestions have found reflection in the reports of bodies appointed to examine important aspects of our present discontents. We have, for example, commented in previous issues upon the findings of the Hadow, Malcolm, and Balfour In all these reports the need for Committees. strengthening the link between education and industry has been emphasised. That emphasis has not come only from official committees. all sides enlightened teachers and leaders of industry have been seeking to join forces. The Emmott Committee of Inquiry into Technical Education and Industry has been, perhaps, the venue of the most varied representatives desiring to commence the solution of this particular problem; and at the recent meeting of the British Association, education and industry was a subject to which a complete session was devoted. Papers read by educationists and industrialists showed clearly that their interdependence is realised by both sides. Especially was it made clear that educational machinery, capable of great development, already exists to supply the requirements of industry, even though no national administrative machinery, through which both sides can adequately express their needs, has yet been formu-Clearly, however, the rapprochement of education and industry has commenced.

The papers to which we have referred were well selected. From the educationist's point of view, arguments were presented for the grouping of social, industrial, and educational problems; the work, general difficulties, and possibilities of a typical technical institution were outlined; the results and advantages obtained by a college which trains engineers on a definite production basis rather than an 'exercise' basis were described. From the industrialist's point of view, criticism of present elementary and secondary school curricula was advanced and a plea was made for a revision

which might give capable managers and workers to industry no less than balanced and thoughtful citizens to society, suggestions were made as to industry's contribution of forms of essential education not always included in the forms' processes of the school. Altogether, we gained a very satisfactory impression that ancient antagonisms are disappearing, and that, since the industrialist has now realised the value-commercial as well as social-of education to his industry, and since the teacher—at least on the technological side—is prepared to shape his work in the wide interests of industry, it appeared to be but a matter of time until the resulting benefits will be enjoyed by student, worker, teacher, and employer.

We must pause here, however, and examine present facts, and not be swept away from them by pleasant speeches and urbane agreements. Industry has commenced to demand men and women soundly educated and expertly trained for its tasks. The educationist has answered by producing from his universities and technical institutions the type of student the industrialist tells him, and which he believes, is required. But if industry has correctly expressed its needs, and education can fulfil those needs, there ought not to be the slightest difficulty in placing every properly qualified student. That is surely an 'acid test' of the relationship between school and employment.

What, however, are the present facts? In chemical industry, for example, we have been told that there is an almost unlimited field for the technically trained man or woman. But those of us who have some knowledge of the number of graduates in chemistry leaving universities and technical institutions also know the difficulties they often have in securing satisfactory employment. How many graduates in engineering, too, have been able to secure positions in which their training can be adequately used? On the commercial side we recall the demand made by employers for highly trained and broad-visioned employees which resulted in the institution of the Bachelor of Commerce degree; but we have not lacked evidence that possessors of that qualification have not found it easy to secure posts in competition with applicants of no other training than that of commercial experience since the age of fourteen years. It is not to be doubted, we think, that there are well-qualified men and women unable to find openings in industry and commerce, and although we realise that the problem of employment has many aspects, we feel bound to ask

whether employers are prepared *now* to take advantage of education's newest product.

It would clearly be a doubtful move to extend the facilities for special training if the present utput cannot be absorbed Are there, then, sufficient openings at present to justify the extension of facilities for which employers ask? Do the majority of employers sufficiently realise the advantage of securing the well-trained recruit? The employer who has done so seems to be the established and, perhaps, leading industrialist who presents what is assumed to be a complete industrial view before public meetings and official and other committee But what of the employers of whom we hear but little and who have not yet understood the sound benefits which can be secured from trained workers? If it be answered that all employers understand those benefits, then the difficulty of securing employment must be traced to a weakness lying elsewhere For, clearly, while the present position continues we cannot avoid the conclusion that the weakness lies either in education or in industry If it be in education, the employer should indicate it with all speed: if it be in the organisation and methods of industry, they must either be altered or else clear instructions, based upon them, must be submitted for the consideration of educationists.

There is certainly one point arising out of the organisation of mdustry which was touched upon during the British Association discussion by an educational and by an industrial representative. The former referred to the growing impression that promotion to the higher posts in engineering proceeded more readily from the office than from the works, and that this industry is already losing heavily by bribing its best boys into the administrative rather than the production side. The latter underlined the same complaint. No amount of inducement, he said, seemed able to overcome what appears to have become a distinct difference in status. This fault of shaping the bright boy to the black suit was regarded as belonging to parents and teachers rather than to employers. But are parents and teachers to receive all the blame? Is it not generally true that difference of status exists? Is it not generally true that in times of bad trade it is the production side which suffers while the administrative side enjoys something very like permanence? Can the employer help to avoid this—a very real threat to the future skill and welfare of industry?

We hope we shall not be misunderstood We have sketched the need for an educational system

which shall fit modern civilisation particularly through its effect of wiping away the ignorance which may fog and warp the issues which are shaping the future We have insisted that the linkmg of education and industry is an essential part of that new system. We have welcomed the evidence which shows that its necessity is being more and more realised; and if we have paused to examine present difficulties which tend towards the nullification of the promise that evidence holds out, we have not done so merely to apportion blame or praise to any particular quarter. It is simply that, in our earnest desire that these new and beneficial movements shall proceed unhampered, we have attempted to indicate some barriers which need speedy removal.

## Science and Theology.

- (1) Concerning Man's Origin · being the Presidential Address given at the Meeting of the British Association held in Leeds on Aug. 31, 1927, and recent Essays on Darwinian Subjects. By Sir Arthur Keth (The Forum Series) Pp. ix +54 (London · Watts and Co, 1927.) 1s. net

   (What I Believe Series) Pp. 392. (London: Ernest Benn, Ltd., 1927.) 8s. 6d net.
- (3) The Church and Science: a Study of the Interrelation of Theological and Scientific Thought. By Dr. Hector Macpherson. (The Living Church Series) Pp. 254 (London James Clarke and Co., Ltd., 1927) 6s net.
- (1) SIR ARTHUR KEITH, in a foreword to his presidential address to the British Association, just published by Messrs. Watts and Co., makes a notable observation. He writes that although the outburst in the public press which followed his defence of Darwinism indicated "that Daytonism is very much alive throughout the land, and that the only science people are prepared to accept is that enshrined in the book of Genesis," yet, that he was encouraged by the reception given to his address by the leaders of religious thought. The words in which he places this upon record are sufficiently important to quote in full:
- "Far from being in opposition, they want to know all that can be known of the universe in which we live, and of that remarkable aberrant product of Nature which we call Man. They have grown up m the post-Darwinian period, and no longer regard the great army of science as an enemy, but as a friendly power. They realise that religion cannot stand still, that it too must evolve, and that it is the duty of theologians not to expect scientific men

to modify their facts to fit religious views, but that religion must be modified to fit man's changing needs, and to be mkeeping with the truth as revealed by scientific inquiry. It may take long before we reach perfect accord, but nothing but good can come out of a working agreement effected between men who are striving for the betterment of humanity through an increase of well-ascertained knowledge. Religious leaders and men of science have the same ideals, they want to understand and explain the universe of which they are part, they both earnestly desire to solve, if a solution is ever possible, that great riddle Why are we here?"

Sir Arthur Keith is undoubtedly justified in believing that religious leaders, so far as the natural sciences are concerned, are by no means reluctant to accept new ideas. If this is gratifying to men of science, it is equally encouraging to theologians to observe among men of science an increasing tendency to take religion seriously and to attach importance to the religious view of life. Nor is this the case only, as might perhaps have been expected, among anthropologists and psychologists, to whose subject matter religion belongs, it is no less conspicuous among physicists and biologists

(2) Among biologists, the latest example of one taking an interest in the religious problem is Prof. J. S. Huxley, who has published his views in a volume entitled "Religion without Revelation" The book is inspired by the belief that

"One of the most urgent needs of humanity at the present time is a common outlook, comparable in its comprehensiveness and wide acceptance with the common outlook, religious and philosophical, which dominated the Middle Ages."

Prof. Huxley does not fail to indicate what he believes should be the foundations of a reformed theology; these will be threefold, and will consist " of agnosticism, of evolutionary natural science, and of psychology." We may presume that the word agnosticism is used in a wide and general sense to describe an attitude which is mistrustful of all dogmatic systems, positive or negative, which are prisons of the mind. With regard to evolutionary science, Sir Arthur Keith's address makes it clear that Darwin's theory of man's origin is not only unshaken but unshakeable; and we may take it that the evolutionary outlook has come to stay. As for psychology, it is clear that a systematic study of the facts of religious experience is a necessary basis of any sound theology.

Our comment may suitably take the form of examining each section of the triple basis in turn. With regard to agnosticism, we are inclined to wish that Prof. Huxley had avoided the word. It conveys the impression that those who use it doubt

whether any large measure of trustworthy truth is available where ultimate questions are concerned. If the historically untenable idea of a supernaturally revealed dogmatic system is to be replaced, some new theory of the attainment of religious knowledge will have to be provided. We fear that Prof. Huxley does not clearly envisage the nature of the problem with which those who believe in religion without believing in 'revelation' are faced That problem is the provision of an altogether new theory of revelation.

With regard to evolution, the introduction of this conception into our thinking is in reality the only sure safeguard against dogmatism, and makes anything like systematic agnosticism unnecessary. Evolutionary ways of thinking have imported some measure of relativism into our ideas without endangering the indispensable notion of objective truth. They have banished dogmatism without introducing scepticism As Prof Huxley puts it

"Thought evolves equally with life. Religious systems which were inevitable products of humanity's childhood or of his adolescent thinking . . . are not for that reason final. Ideas which in their time and season meant immense advance . . . may actually become harmful when circumstances alter and the old ideas are found to be hindering the progress of new and better ideas."

Then, with regard to psychology, the last part of the threefold basis. We owe a great debt of gratitude to Prof. Huxley for having included an autobiographical chapter in his book. It is to be feared that some men of science have written of religion while having very little first-hand experience to guide their speculations. This is not the case with Prof. Huxley, who seems to have been through religious experiences which only differ from the normal by being more intense His experience seems to have taken the form of nature-mysticism united with fervent moral idealism, but apparently unconnected with the dogmas of 'revealed' religion, from the teaching of which his childhood had been free. (It is to be noted, however, that he was brought up in an atmosphere of vigorous moral earnestness, quite different in character from much of the frivolous irreligion of the present day)

In view of all this, it is a little of a disappointment to find Prof. Huxley inclined to surrender his experience to the inadequate and rather shallow interpretations of the psychologist, who, to be sure, is too much with us to-day He writes:

"They [the religious experiences] and my reading also convinced me that the revelation of the mystic vision is revelation only in a psychological sense, not literally. There need be no supernatural

being or force making the revelation; nor is the revelation one of an external reality."

This last sentence, however, seems to be quite unhelpful dogmatism. It would have been more profitable, and more scientific, to inquire what kind of truth mystical insight may be expected to supply us with, whether similar in kind to that supplied by æsthetic or moral insight, or otherwise. In point of fact, some philosophers, quite innocent of theological bias and without the qualification of having enjoyed Prof. Huxley's remarkable religious experience, are inclined to attribute considerable significance to such phenomena. Mr C D. Broad, for example, though confessedly almost devoid himself of such experiences, has expressed his belief "that they are probably of extreme importance in any theoretical interpretation of the world"

It is a curious fact that about the real bone of contention between religion and science at the present time, that is, miracle, Prof. Huxley says scarcely anything. This is at present the crux. It is as it were a correlative to revelation, as this is the supernatural in the sphere of knowledge, so the miracle is the supernatural in the sphere of action. In what sense, if any, we can hold to either of these conceptions needs thinking out very carefully

(3) Dr Hector Macpherson, in his book "The Church and Science," does devote a chapter to the miraculous. He points out that the reformers took over Aquinas's conception of miracle, which at least had the advantage of being clear and definite, it was an event having its cause outside Nature. The difficulty, of course, is that until you know the whole of Nature, you cannot tell what lies outside No man of science will consent to adopt this method of explanation, as it stultifies his methods entirely. Dr. Macpherson quotes extensively from Mr J. M. Thompson's "Miracles in the New Testament," a book which made a considerable stir when it appeared in 1911 Thompson's view was that the doctrine of the Incarnation can stand quite independently of miracles; but as he was inhibited by the Bishop of Winchester at the time, it does not look as if his views were accepted by the ecclesiastical authorities As a matter of fact, the book was a careful piece of textual and literary criticism of the New Testament documents concerned, and its reception showed that orthodox theology had not yet come to terms with the critical study of literary sources other words, the religion and science conflict has settled down at present to a controversy between scientific history and theological history.

J. C. HARDWICK.

# Cultures and Migration.

Psychology and Ethnology. By Dr. W. H. R. Rivers. (International Library of Psychology, Philosophy and Scientific Method.) Pp. xxviii + 324. (London Kegan Paul and Co., Ltd., New York · Harcourt, Brace and Co., Inc., 1926) 15s. net.

THIS volume is one of a series entitled "The International Library of Psychology, Philosophy, and Scientific Method." Rivers was above all a master of method, and had he lived to write a book on method in the historical investigation of human cultures, he would have added to the already great debt anthropologists owe him. The present work is a collection of lectures and essays, dealing mainly with the constant theme of the historical school of anthropology, the unity of culture. The greater number were delivered to somewhat mixed audiences, hence there comes about an almost wearisome reiteration of the hypotheses, and perhaps—apart from pan-Egyptianism —some over-emphasis of the differences between the views put forth by the historical or diffusionist school and by other anthropologists. The chapters have not been arranged chronologically to show Rivers's contribution to method—indeed, his first and by far his most important contribution, "A Genealogical Method of Collecting Social and Vital Statistics" (Jour. Roy. Anthrop. Inst., vol 30, 1900), has been omitted—but come under a few selected headings.

The reader who bears with these disadvantages will be rewarded, not with the proof or disproof of the theories of the extreme diffusionists, but by the discovery of some of the principles and results that Rivers worked out when studying the contacts of peoples in Melanesia, where he carried out the plan he had previously elaborated for obtaining exact information; that is to say, he used the genealogical method with the study of kinship as the basis of investigation. When he examined his material he came to certain conclusions which may be looked upon as his chief methodological results, in this review arranged and to a limited extent discussed under numerical headings:

(1) That social structure, the framework of society, is fundamentally important, and not easily changed except as the result of the *intimate blendings of peoples* or of the most profound political changes, and for that reason furnishes the firmest foundation on which to base the process of analysis of *culture*. The relative permanence of

the social structure is so great that its course of development may furnish a guide to the action in order of time of the different elements into which it is possible to analyse a given culture complex (pp. 135-8). These two sentences are condensed from "The Ethnological Analysis of Culture," but the italics are my own.

Yet, if I understand aright the general trend of these essays, Rivers later accepted a more extreme diffusionist view, namely, that cultural changes were introduced by the carrying about the world by small bands of foreigners of definite elements, independently of any general cultural blending. On the other hand, a collection of essays offers no such continuous structure that it is possible to be certain that Rivers had entirely realised the full significance of the acceptance of this proposition, which logically would lead to the rejection of so much of his previous work. Such wholesale modification of viewpoint seems scarcely likely, for Prof. Elliot Smith himself has said in the preface to "Social Organisation," published in 1924. "On his own admission his work on social organisation was his greatest achievement in his chosen field of investigation," so we may perhaps regard "blending" as not consciously jettisoned, though in many instances Rivers no doubt did accept the free transmission of foreign elements. As an example of the kind of difficulty referred to, it is sufficient to compare the views on the dual organisation put forward by Rivers on one hand and by Prof. Elliot Smith and Mr. Perry on the other, who regard the dual organisation of society as one of the elements of culture that arose in Egypt and was carried about the world (Elliot Smith, "Encyclopædia Britannica," vol. 30, article "Anthropology"; Perry, Appendix 3 to Rivers's "Social Organisation"). These views may be contrasted with the treatment of dual organisation in the "History of Melanesian Society," for example, vol. 2, p. 250.

(2) The second principle is that involved in the disappearance of useful arts; this is a feature of the degeneration of culture which plays so large a part in the scheme, and is one which had long called for examination. Here we may direct attention to one aspect of the controversy which might be overlooked by those who are only interested in the proof or rejection of the general idea, namely, that it is the 'common sense' view that man is guided by reason which is here refuted. In the examination of the causes of the disappearance of the canoe from the Torres Islands and Mangareva, Rivers was led to reject material and

social factors as insufficient in themselves, and he saw in the loss of the magical and religious rites accompanying the craft the loss of the craft itself. He does not, however, suggest any reason for the loss of the magic.

"Quite as striking as the loss of useful arts is the extraordinary persistence of elements of culture which seem to us wholly useless . . . this . . combines . . . to make us beware of judging human culture by purely utilitarian standards" (p. 208). One of the difficulties here is to recognise what to the savage is a purely utilitarian standard

(3) The extent of the influence of one people upon another depends upon the difference in the level of their cultures. A very small number of immigrants of a sufficiently high culture can have a relatively enormous influence on a low culture. This is the principle relied upon for the spread of the megalithic culture in the essay entitled "Contact of Peoples," and comparison is made of European influence on peoples of the lower cultures on one hand and on those of India and China on the other.

(4) The motive for migrations determines their distribution, which might otherwise appear fortuitous Rivers accepted Mr. Perry's theory, that the motive was the search for wealth or life-giving substances · "The force was attractive rather than propulsive, viz. the love of wealth, which is still the most potent factor in immigration" (p. 171) This was probably not intended as a principle to be taken without other subsidiary factors, for though the love of wealth may always be present, immigration is periodic. Moreover, when particular instances are examined the thesis is likely to break down, as in the example afforded by the recent discussion on pearls in Man; again, it is doubtful whether the love of wealth had any considerableinfluence on the first great spread of Islam, though trading and slave raiding undoubtedly assisted or even led to later movements.

(5) Ancient beliefs tend to be preserved with greatest fidelity not near their old home but in remote spots, among people of a simple mentality. This conclusion was drawn after the construction of a hypothetical scheme to account for belief in 'soul-substance' in Melanesia (including New Guinea), as well as for the burial customs of San Cristoval in the Solomon Islands. The reason adduced is the simple mentality of the people, which leads them to "accept without any great modification beliefs which take their fancy, while the absence or scarcity of later external influence

prevents the modification, or even obliteration of beliefs, which are always liable to occur among more sophisticated peoples and in regions more open to the play of external influence" (p. 118). This principle, the parallel to that of the distribution of living animal forms from a geological centre, seems to have been elaborated independently. With all necessary reserve, the reviewer would place on record his belief that of late anthropologists have tended to underestimate the fluidity of native custom and its capacity, nay its tendency, to modification within its own sphere of activity without foreign stimulus.

(6) "Wherever we find diversity of funeral rites, we may safely conclude that there has been diversity of culture" (p. 163). This conclusion is drawn from the general observation that rites, ideas, and beliefs concerning the dead are among the most sacred of human reactions, and held with the greatest conservatism. The diversity of funeral rites in Australia is one of the main causes that led Rivers to suspect the complexity of Australian culture.

Handled with caution, all of the above are useful principles, but the need for caution cannot be overrated. For though the diffusionist school that Rivers upholds in this volume is sometimes called the historical school, its relation to history is precarious and depends on a number of bold The existence of the Egyptian assumptions. culture is an historic fact, its connexion with the megalithic culture a courageous deduction with which archæologists in general disagree. Moreover, the migrations from Egypt with which the diffusionists deal are all ignored by historic records, nor has a single specimen, not even a potsherd, of Egyptian or Near Eastern manufacture been found in those localities supposed to have been most subject to Egyptian influence. The assumed motives of the migrations are yet bolder. Present customs are explained in the light of hypothetical migrations, and the megalithic culture itself explained by comparison with modern custom. The danger of the vicious circle is obvious, yet this statement should not be taken to imply that we need be satisfied with the methods of anthropology before the florescence of the diffusionists No doubt there is much to be learnt by the careful application of Rivers's principles to some known historic movement, as, for example, the spread of Islam. The different phases in its extension could be studied; its conquests and its forms of peaceful penetration contrasted, and the varying results examined. Such an examination

might even justify some of the more far-reaching speculations of the school. Above all, such studies, starting from definite historical facts, and continually checked by these, should throw light on the formation of new culture complexes, and thus to some degree act as a test of the validity of the hypothetical schemes put forward by the diffusionist school.

C. G. Seligman.

# Two Fundamental Problems in Physical Chemistry.

Physico-Chemical Metamorphosis and some Problems in Piezochemistry By Ernst Cohen. (The George Fisher Baker Non-resident Lectureship in Chemistry at Cornell University.) Pp. vi + 190. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1926) 2.50 dollars.

PROF. ERNST COHEN of Utrecht went to Cornell University early in 1926 as the first holder of a non-resident lectureship in chemistry, supported by an endowment given for this purpose by Mr. G. F Baker. His introductory lecture, under the title "Qua vadimus?" has already been circulated to many workers who receive reprints from the van't Hoff Laboratory at Utrecht; but it now appears as the precursor of ten lectures on "Physico-Chemical Metamorphosis" and eleven lectures on "Some Problems in Piezochemistry."

The first series of lectures deals with the transformations (and especially with the suspended transformations) of tin, antimony, cadmium, thallous picrate, cadmium rodide, and ammonium nitrate In all these cases the author provides evidence of the difficulty of securing the complete transformation of a polymorphic solid into one of its possible forms, and the risk that, if sufficient precautions are not taken, the physical data recorded will be those of a mixture of the various forms. This risk must be admitted, but not to the extent of producing a pessimistic outlook, since inconstant results generally provide an efficient danger-signal when a condition of complete equilibrium is not being attained in any given series of experiments. The cases cited, which include those of 'tin pest' and 'explosive antimony,' are, however, of a very interesting character, and include some of the most dramatic results of the author's own researches.

The second series of lectures is chiefly remarkable for the skilful handling which it discloses of the difficult problems encountered in carrying out the common operations of physical chemistry under a pressure of 1500 atmospheres. Under these

conditions, determinations of reaction-velocity, solubility, electromotive force, electrochemical equivalent, velocity of diffusion and viscosity, all call for the invention of appropriate apparatus, embodied in workmanlike designs, for making measurements of a high order of accuracy, whilst paying due regard to the possible effects of contamination by the fluid through which the pressure is transmitted to the system under investigation. It is therefore not an adverse criticism to say that more interest and instruction is to be found in reading how the experiments were made, than in nothing the character of the numerical results that were recorded. It is, indeed, almost a disappointment to read of the unfailing regularity with which the predictions of thermodynamics were fulfilled, since a few violent exceptions would have added an element of sport to what is now an almost monotonous record of difficulties surmounted and goals attained.

Those who know Prof. Cohen's linguistic and literary skill, and in particular his perfect mastery of English, together with the winsomeness of his appeal to his hearers, can paint a vivid picture of the attractiveness of the course of lectures to those who had the privilege of listening to them. The printed record will, however, be read with pleasure by a much wider circle of interested students and teachers, since it provides in a convenient and attractive form the equivalent of two monographs on subjects of wide general interest. T. M. L.

#### Our Bookshelf.

The Making of a Chemical: a Guide to Works Practice. By E. I. Lewis and Geo. King. Pp. 288. (London: Ernest Benn, Ltd., 1927.) 12s. 6d. net.

It must be something like twenty years since Mr. E. I. Lewis achieved fame as the author of an inorganic chemistry, which differed widely in character from most of the text-books that had been written previously. Mr. Lewis's book was specially designed for the needs of boys coming over from the classical side, who did not need to acquire a professional knowledge of the subject, but were expected to secure some measure of scientific culture from its study. His book proved, however, to be of wider value, in that its broad and philosophic treatment made it a suitable revision book for many students who had taken an elementary course, but without acquiring the fuller knowledge of the foundations of his faith, which one looks for in a university worker.

The schoolmaster has now become an industrialist, but without losing either his literary skill or his desire to teach the rising generation. He has, therefore, in collaboration with a colleague, written a book on "The Making of a Chemical,"

m which he gives much excellent advice to the student who is about to enter, and hopes to find a career in, chemical industry. His advice is so good that, if it were all put into practice, the product would be almost too perfect to be useful; it has certainly had the effect of leaving the reviewer with a sense of his own unworthiness to undertake so high and holy a vocation, and to marvel at the lofty heights to which the authors of such a book must themselves have attained.

On the other hand, if the reader is prepared to leave good advice to suffer its usual fate, he will find that the book contains a very useful sketch of the fundamental problems of chemical preparation when carried out on a large industrial scale, and a very readable summary of the typical solutions of these problems. Even more useful, perhaps, is the frequent reference to technical books, since the academic student, who knows how to track down original references with the help of Beilstein and the British Abstracts, may very easily be floored by the problem of finding out where to go for a trustworthy review of the best current practice in some branch of chemical engineering. The authors, one may suppose, have themselves tested and vindicated the usefulness of the books which they cite, and they will have rendered a real service to the young industrial chemist if they are able to guide him in the early stages of building up a technical library of his own.

Sex and Repression in Savage Society. By Bronislaw Malinowski. (International Library of Psychology, Philosophy and Scientific Method.) Pp. xv+285. (London: Kegan Paul and Co., Ltd; New York: Harcourt, Brace and Co., Inc, 1927.) 10s. 6d. net

In this volume Prof. Malinowski restates his position in relation to the Freudian doctrine of the Œdipus complex, showing how that theory of father-and-son antagonism and a mother-and-son attraction based upon a sexual impulse, having been formulated in relation to a patrilineal society, breaks down when applied to the behaviour of peoples organised on matrilineal lines. He then passes on to the consideration of the nature of the influence of the family complex on the formation of myth, legend, and fairy tale, on customs, form of social organisation, and achievements of material culture, and finally passes to what is the most important contribution of his book to this subject, the consideration of the origins of culture, where he finds himself on the borderland between the animal and the human.

On the view that the instincts are plastic, and can be and are moulded by cultural influence, what the Freudians regard as fundamental, the manifestation of the sex instinct and its repression, become incidental. When it appears it is a maladjustment. Prof. Malinowski's conclusion, therefore, is that the building up of the sentiments and the maladjustments which this may entail depend largely upon the sociological mechanism working in a given society. The main aspects of this mechanism are the regulation of infantile

sexuality, the incest taboos, exogamy, the apportionment of authority, and the type of household organisation. This contribution by Prof. Malmowski to the discussion of Freudian doctrines is one of considerable importance, based as it is upon material actually gathered in the field, but it will be a matter for regret if its polemical character in part obscures the fact that it is one of the author's most original and suggestive contributions to anthropological theory

Beitrage zur Kenntnis der Verbanderung und einiger verwandter teratologischer Erscheinungen. Von Dr. Const. C Georgescu. (Botanische Abhandlungen, herausgegeben von Prof. K. Goebel, Heft 11) Pp. 120 (Jena Gustav Fischer, 1927) 6 gold marks

This little work on fasciation contains some experimental and observational results and an incomplete bibliography of the subject. The author points out that fasciation may occur as a modification caused by excess nutrition, attacks of insects, etc., but that it is more commonly a mutation. Celosia cristata, the cockscomb of gardens, is an example of such a species. Its origin is unknown, although it is now cultivated all over the world, but it was known to Pliny. In culture solutions lacking particular salts, no effect was produced, except that the absence of calcium prevented flowering Races of Celosia differed in the degree or amount of fasciation, and bad conditions reduced the number which showed it Experiments were also made with Sambucus nigra.

Fasciation may occur in stems, roots, flowers, fruits, or even stigmas. The author classifies fasciations as dorsiventral or bilateral, which can be anatomically distinguished. Two types of shoots are also distinguished, in one of which there is flattening throughout, while in the other only the tips of the branches are flattened. Fasciation results in abnormal phyllotaxy, and a morphological study is made of this condition, especially in Sambucus and Celosia R. R. G.

Balancing the Farm Output: a Statement of the Present Deplorable Conditions of Farming; its Causes and Suggested Remedies. By Dr. W. J Spillman. (Farm and Garden Library.) Pp.126 + 10 plates. (New York: The Orange Judd Publishing Co., Inc.; London: Kegan Paul and Co, Ltd., 1927.) 1.25 dollars.

The title of this little book indicates that Britain is not the only country in which farming is in a deplorable condition. The cause is the same; current prices run below costs of production. Many remedies have been suggested, and it is surprising to learn that so many countries have adopted various schemes of what our author terms 'valorisation,' that is, an artificial raising of home prices by State action. In regard to all these schemes the author prophesies disaster. In their place he would substitute a scheme of which it is sufficient to say here that it predicates a degree of State interference with private business which—if endurable in an autocratically governed country

like the U.S.A —would not be tolerated in Great Britain. The book, however, is valuable as a reasoned summary of schemes for remedying an undoubtedly serious state of affairs. For ourselves, we would rather pin our faith on the march of knowledge. if practice is outworn, our only hope is science and, again, more science.

Geologisches Praktikum Von Prof. Dr. Rudolf Sokol. (Sammlung naturwissenschaftliche Praktika, Band 13) Pp. viii +248. (Berlin: Gebruder Borntraeger, 1927.) 14 50 gold marks.

Prof. Sokol completed this book in December of last year, but unfortunately he did not live to see its publication; two months later he passed away. The obstuary notice which has been added to his book pays high tribute to his great reputation as a teacher, and the book itself calls for equal praise. After insisting that a geological training demands a preliminary acquaintance with many other branches of scientific knowledge, the subject of map-reading, topographical and geological, is introduced. Instruments are next passed in review, and this section includes an account of the use of the Eotvos balance. Materials are treated at some length; their collection, preparation, and investigation, their nature and distribution and relative ages. Structural geology occupies a third of the book, and the section dealing with faults, their measurement and description, is particularly valuable. Suggestions are given for making and noting observations in the field; for making maps; and for writing up reports. The concluding sections deal briefly with materials of economic importance. A short bibliography is appended, but this is unsatisfactory, since it contains no references to British works. The book is strongly bound and effectively illustrated

The Physiography of the Region of Chicago. By F. M. Fryxell. Prepared by the University of Chicago Local Community Research Committee, and the Chicago Commonwealth Club, for the Committee on General Surveys of the Chicago Regional Planning Association. Pp viii +55. (Chicago, Ill.. University of Chicago Press, London: Cambridge University Press, 1927.) 12s 6d. net.

This very careful study of the physical geography of the Chicago region is a model of the kind of foundation that is desirable for regional survey work, and as such it is likely to be of special value to the many British workers and teachers who are similarly interested in their own neighbourhoods. It is also of more general interest in containing many excellent diagrams and a series of folded maps showing relief, drainage, glaciation, and soils The topics discussed include the great industrial area of the lake plain; the surrounding recreational areas; the pass to the Mississippi valley, the continental divide; the shore line of Lake Michigan; the buried landscape of the bedrock; the agricultural areas and soils; and the geological resources. A large base map specially prepared under the direction of Prof. J. P. Goode folds into a pocket on the back cover.

## Letters to the Editor.

#### The Mathematics of Intelligence.

It has been said by Kant that a science is genuinely scientific in so far as it involves mathematics; and interesting light is thrown on this dictum by considering it in reference to the various attempts that have been made to introduce mathematics into psychology. First came the grandiose effort of the Herbartian to depict mathematically the interaction of ideas. This tailed for total lack of experimental support. Then followed the great and very successful attempt of Weber and Fechner to measure sensory discrimination. Much more recently, there has been an invocation of mathematics for the purpose of analysing mental ability. As this last attempt is now very much perturbing psychologists all over the world, let us consider it in a little more detail.

In the year 1904, on the basis of a mathematical theorem coupled with some actual observation, the doctrine was advanced that the measure of any individual in any ability could be divided into two factors; the one was common to all the abilities concerned; whereas the other was specific to the one ability alone. These two factors were designated by the letters g and s; and the extremely important corollary was drawn that, by averaging together many dissimilar mental performances, the influence of the s's would tend to cancel out, leaving an approximate

measure of the pure g.

This doctrine was very unexpected, and gave rise to an acute controversy which has continued ever since. On the mathematical side, the objections raised have one by one been either refuted as pointless, or else met by further developments. On the side of observation, the scope has been continually broadened. Originally, the work had been limited to a single experimenter dealing with little more than 100 individuals, all of whom were young boys. But already in 1912 the range had been extended to 14 experimenters treating 1463 boys and girls, men and women, sane and insane. At the present day, this number of experimenters has certainly been quadrupled, whilst the number of individuals has grown to many scores of thousands. Finally, the attempt was made by me in a book entitled Abilities of Man" (Macmillan, 1927) to bring all this work into one systematic whole. The interpretation of g found to account best for all the observed facts was to conceive it as measuring some general 'energy responsible for all the activities of the mind. s's, on the other hand, were taken to be the various 'engmes' into any of which the energy could alternatively be directed.

In addition to the g which thus measured the quantity of the mental energy, there was also determined a value p which measured the degree of the 'inertia' of this energy; and furthermore, an o which measured the degree that the supply of the energy tended to oscillate. These three measures conjointly were said to furnish the cardinal features distinguishing the abilities of one individual from those of another. The evolution of the doctrine went further still, carrying it far beyond the whole sphere of psychology known as that of individual differences. For during the time that the facts belonging to this

sphere were being investigated, those appertaining to 'general psychology' were being treated from a fundamentally novel viewpoint (that of the doctrine known as 'noegenesis'). The surprising result was that these two spheres, hitherto kept by psychology in disastrous divorce from one another, now litted as hand and glove Finally, both these spheres of cognition, that of individual differences and that of general psychology, have in the continued development of the doctrine of g and s become organically united with that other great domain of the mind which is not cognitive but conative; it does not deal with knowing, but with striving and deciding. To the gand the s's of the energy and the engines, there has now been added a w, which brings all these into action, playing thus the part of the 'engineer.' Accordingly, the entire movement having as its core the concept of g has constituted a great endeavour to supply psychology at last with a unified, complete, and genuinely scientific foundation

A review of "The Abilities of Man" was published in Nature of Aug. 6, the reviewer adopting an extreme attitude in the now rapidly dwindling opposition party. For my part, I welcome this review in so far as it expresses the chief lines that may still be taken up against the book. But I cannot help regretting that it should present an entirely incorrect picture of what is given in the book itself. In the first place, there is the grave default that the foregoing immense scope of the work done—just the scope that the book expressly set out to narrate—is not even hinted to the reader of the review; and then this, on the positive side, is throughout strangely permeated with vital misapprehensions, as will be seen by taking each of its

points in turn.

1. The beginning of it is a general complaint that the statements in the book cannot be adequately verified for lack of sufficient arithmetical data and mathematical demonstrations. But it must be replied that data are really furnished in very great quantity, so that any one can check the arithmetic as much as he pleases; while all the chief mathematical demonstrations are given fully in the appendix.

2 Next, the objection is raised that the book criticises the definitions of 'intelligence' given by other people, but fails to supply one itself. Really, the tenor of the book was to suspend usage of the highly equivocal word 'intelligence' and to show unequivocally what mental powers actually exist. Then, indications were furnished as to which of these powers might be entitled intelligence most reasonably; but the suggestion was made of abolishing the word

altogether.

3. After this, the reviewer commits himself to a very serious statement. The book, he asserts, 'hypothecates' that the measurement of an ability is a function of two factors and then proceeds to replace this general functional relation by a purely linear one. In answer, he must be referred to the actual mathematical demonstration (appendix 111-v). This really contains no such hypothesis, no such replacement, nor anything like them; but instead, a full proof that when the correlations are what has been called 'hierarchical,' then the measurements can be expressed as linear functions of the two factors. As much may be said of the earlier proof supplied by Garnett.

4. Neither proof implies even Taylor's theorem directly. Such an implication is only indirect and occurs only to the extent that this theorem may underlie the significance of the whole theory of correlation and even of 'normal' frequency. In the book I ventured to throw out the suggestion that the

theorem may be thus implicated in the theory of correlation. But I do not press this matter for the present. I only mention it here as I wish to admit trankly that the book did not make this distinction between direct assumption and indirect implication

nearly clear enough.

5 The reviewer's next point is that a certain important quantity called the 'tetrad difference' was assumed by the book to have a normal frequency, whereas, he says, the data in the book itself prove that the distribution is not normal. In truth, the book never made any such assumption, instead, it showed graphically that the frequency is normal with good approximation.

6. He then objects that the mean tetrad difference had been made by me zero artificially. In truth, the mean of all the tetrad differences from any set of

variables is zero necessarily.

7. Then the reviewer lays down that the only real test provided of the agreement between theory and observation is a comparison of the probable error of the tetrad differences with their observed median value; and this test he considers not to have been passed with manifest success, since (in the case he picks out) the probable error was 0 061 and the observed median 0.062 (or, according to him. 0.060 and 0.058 respectively) The reply must be that such two values do manifestly 'fit' each other very well indeed. In last resource, all evidence of good fit between theory and observation consists in thus simply juxtaposing the two values and seeing whether they are nearly equal. Certainly not often is the result more favourable than the above one

8. In truth, however, this is by no means the only real test possible or provided. In statistics the probable error is compared, not only with the median of the observed values, but also with each of these values separately. This is what had been done throughout the book in treating the entire mass of available data published on the subject by the multitudinous investigators (including those belonging to the opposition party itself). The result was to show that whenever any tetrad difference did become excessive, then there were always good psychological grounds for it being so; the circumstances of the case were such as to require by theory that this particular tetrad difference should not be zero.

9. The reviewer closes by remarking that a better way to approach the problem would be to consider that, if we could assume the probable errors of the different tetrad differences to be mutually independent, then "We should . . . conclude that the new . . . theory, so far from being in 'striking agreement' with observation, signally failed." To this the answer is that, since any such assumption of independence is obviously quite wrong, the advantage of this new way of approach or even the point of suggesting that then the theory

would fail—is not evident.

Let us, however, now consider how far the present occasion can be utilised for converting mere wrangle into scientific progress The cardinal points (3) and (6) are matters of pure mathematics; they therefore can and should be definitely settled Unless, then, the reviewer is convinced by the foregoing remarks, Unless, then, I suggest that an impartial committee be appointed to adjudicate upon these two points and to report m this journal. As for the machinery of appointment, perhaps it could be done by a joint meeting of representatives of the Mathematical and Psychological Sections of the British Association. Points (1), (2), and (5) are misapprehensions which a closer study of the book ought easily to remove. But should the reviewer, after having heard my own account of what

I wrote and meant, still insist that his version is more correct, then these points too might be submitted to the committee. As for points (7) and (9), these, I hope are already sufficiently obvious On the other hand, point (8), involving as it does every part of the book and the whole of cognitive psychology, does not appear to be capable of summary settlement. Since here the crux is far more psychological than mathematical, the issue must be left to the eventual consensus of the general body of psychologists.

C. Spearman.

71 Kensington Gardens Square, W.2

The review in Nature of Prof. Spearman's book stated precisely what was possible in a critique which must not be of mordinate length. The review of the work took what its author in his present communication considers the kernel of his researches and of his recent book, namely, the hypothetical g and s, and considered whether Prof. Spearman was justified in making such sweeping claims for the hypothesis of a general and specific factors. The reviewer held, and still holds, that whether that hypothesis be verifiable or not, the data hitherto cited in favour of it are far from demonstrating its truth. In reply to Prof. Spearman's numbered statements the reviewer wishes to make the following counter statements.

(1) The general complaint that the actual data by which the conclusions in the book can be tested are not provided is correct. It took weeks of work to reproduce the frequency data for tetrads on which the chief arguments in chap. x. are based. When this was done the extent of the agreement was found to be not such as appears in the book itself.

(2) The reviewer's opinion that it is easier to criticise definitions than to provide them will be amply illustrated—at any rate to a physicist—by a study of chaps. ix. and xxiii. of "The Abilities of

(3) and (4) The reviewer can only repeat his assertion that Prof. Spearman has assumed that the functional relation is a purely linear one. The direct appeal to the lowest terms of a Taylor's series is made on p. v, and an indirect appeal to lineanity in pp. in-v of the Appendix to which Prof. Spearman now refers The statement that Taylor's theorem underlies the whole theory of correlation is in-

(5) On p. 146 Prof. Spearman has the following words, beneath a diagram showing a normal frequency curve superposed on a series of rectangles. "This time the two distributions, curve and rectangles, far from being totally discrepant as before, display instead one of the most striking agreements between theory and observation ever recorded in psychology" (Reviewer's italics). The author's words clearly denote that the curve corresponds to theory and the rectangles to observation. If they do not, what is the 'theory' which so strikingly corresponds to observation? It cannot be the two numbers given under the diagram, for one of them depends again on the normal curve.

If the frequency be not a normal curve but a curve which really depends on the individual series of tetrads, what is the meaning of talking about discrepancy 'between other tetrad distributions and the normal curve? A 'discrepancy' can only exist if a theory be known, and if Prof. Spearman's theory be not that of the normal curve, he has no measure of discrepancy. What is his 'theory'?

(6) The reviewer did not object to Prof. Spearman

making his mean of tetrads zero, by taking each one first positive and then negative, but what he pointed out was that having done this and got a symmetrical curve, Prof Spearman in every case was depending upon the value of a *single* constant of this artificially symmetrical distribution to test the accordance of theory and observation. No frequency distribution is defined by a single constant.

(7) This should read of course the "only real test provided" by Prof. Spearman; there are many other possible tests, so soon as we know definitely what his theory of tetrad distribution really is. The terms 'probable error' and 'observed median' appeal directly to the theory of a normal distribution. Values such as 0.060 and 0.058 may or may not be in agreement It depends entirely on what the probable error of their determination may be. Read in hectometres, the average statures of Englishmen and Frenchmen are 0 017 and 0 016 respectively. Do these "manifestly fit each other very well indeed"? Prof. Spearman writes: "In last resource, all evidence of good fit between theory and observation consists in thus simply juxtaposing the two values and seeing whether they are nearly equal. Certainly not often is the result more favourable than the above one." The reviewer ventures to think this remark is erroneous. The true statistical theory consists (i) in deducing a correct arithmetical result from the data, (11) in propounding a correct and comprehensive theory, and (in) in testing by the theory of errors whether the deviation between observation and theory is or is not probable on the basis of random sampling In all three points, in the opinion of his reviewer, Prof. Spearman has failed. His arithmetic is not always, but is often incorrect —his theory of what the variation of the tetrad distribution should be is incorrect—and he never concerns himself with the probable error of the difference between his theory and his observations. In the case of the statures cited above, the probable error of the difference is of the order 0 0002, and this is precisely what occurs in a number of Prot Spearman's cases—three (and sometimes two!) significant figures are not adequate to reach the probable error of the difference, even if that difference were based on a satisfactory mathematical theory.

(9) The answer here is a perfectly definite one. Prof. Spearman looks at two numbers or at a graph and asserts, apparently by mere inspection, that they are in 'good approximation.' The reviewer holds that no such inspection is of any real scientific value; a numerical test of some kind to measure the extent of this agreement must be applied. Where in mere inspection does Prof. Spearman introduce the fact that his tetrads are correlated? How does he allow for it in running his eye over the graph? Is he not judging, as we suspect he must, that his curve fits well his rectangles, however those rectangles have arisen? To test this we supposed those rectangles not to have arisen from tetrads, and we find the fit for such a system of frequency is bad, not good. How does Prof. Spearman, by aid of a special s factor, determine that owing to correlation the eye alone can judge between the two cases and assert that the fit of curve and rectangles is good for tetrads, but would be bad for a series of intelligence quotients on different individuals?

Are we prevented from applying a test of goodness of fit to measurements on a colony of statoblasts because there exists a high degree of hereditary correlation between its individuals? The reviewer wrote in his notice of "The Abilities of Man" that the pages of NATURE could not provide adequate space for a full mathematical and statistical criticism of

Prof. Spearman's hypothesis. The first part of such a criticism is now at press, and will be published shortly.

The Reviewer

[Prof. Spearman has left England for the United States and will not return until January next. He desires it to be known, however, that he proposes to pursue the conflicting statements in this correspondence by means of independent adjudication, as suggested in the concluding paragraph of his letter.—Ed. Nature.]

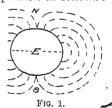

#### Possible Explanation of the Zodiacal Light.

The nature or origin of the zoduceal light is regarded as more or less of a mystery. Some have thought that the phenomenon may indicate the existence of a diffused ring of small particles in equilibrium and in nature somewhat like those of Saturn's rings, though more scattered and existing in very small amount compared thereto. This hypothesis assumes a stability which it is difficult to accord to such a ring

If we assume, however, that the coronal streamers from the sun, which apparently extend without limit of distance into space, are partly composed of or accompanied by fine particles propelled by the pressure of light, or even of fine solids from condensation of vapours arising from the solar atmosphere and expanding into a vacuum external thereto, we may form a hypothesis which seems to be consistent with the facts. The fine condensed particles would move into a vacuous space in substantially straight lines and would reach enormous distances from the solar body. As the spectrum lines of iron are prominent in solar light, it might be expected that in the space surrounding the sun fine particles of iron would constitute, in part, at least, those escaping streamers from the solar atmosphere. These particles would surround the earth and be extended in all directions therefrom.

If they be of the same or of sin dar nature to those which in my experiments are seen to line up in a magnetic field (the observations on the novel magneto-optical effect described in Nature of June 23, 1921, p. 520), then the zodiacal light, which is seen best at places near the equator and at times of vernal and autumnal equinoxes, might be explained as follows: The magnetic field lines of the

The magnetic field lines of the earth joining the north and south areas outside the earth would, at the equator, he sensibly parallel to the earth's axis, but at a great height, on the average, above the surface of the earth. This is illustrated in the subjoined diagram (Fig. 1), which indicates the general trend of the earth's

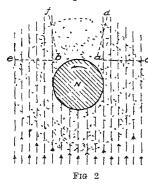

magnetic field (one side only) all around the earth m the space about it

The dots in Fig. 2 do not represent floating particles, but are intended to show only that if one could look at a pole of the earth from a great distance and see a section through the equatorial plane, the lines of force of Fig. 1 might be indicated as dots in the equatorial plane. Now let the sun's rays be from below; it will be seen that they intersect the direction of the magnetic lines at nearly right angles. Now, further, let us by some means render visible in the polar beam the magnetic field about the earth; it will become apparent that it will be best seen by observers after twilight at night and before twilight in the morning—best at the time of the equinoxes and best in the tropical night. On the average, the observer placed at about a or b looking upward, will

be well placed for such observation, and the column of light will extend from c to d on the evening side, and from e to f on the morning side, or over an angle of about  $60^{\circ}$  altitude, more or less

It may, therefore, appear as a plausible hypothesis that the luminous effect known as the zodiacal light or the *Gegenschein* may be of the same nature as that observed in the combination of magnetic field, light beam, and iron smoke from an arc, as described in 1921 in NATURE. If the zodiacal light is polarised in the same way as the light from the iron smoke is polarised, and undergoes the same variations by variations in the direction of viewing it, these circumstances might assist in identification.

There has been no opportunity to make any observations on this point As the luminosity of the zodiacal

light is low, although coming from a great depth of space around the earth, there would not need to exist, for producing the effect, more than an exceedingly small density in the iron particles concerned, a density perhaps millions of times less than in my original experiments on the magneto-optical effect. It has been shown also that the orientation which is the cause of increased luminosity in the light beam is

producible by a very weak magnetic field. That the direction of viewing is transverse to that of the light beam, and that the magnetic field lines are transverse both to the directions of viewing and the light beam, are significant facts. More and varied observations and experiments are certainly warranted in this fascinating field [see NATURE of Oct. 22, p. 581].

It will be seen that the hypothesis presented does not require any ring formation around the earth. It requires only that the general space surrounding the sun and planets contain an exceedingly small density of diffused iron particles, capable of being affected or oriented when in the magnetic field surrounding the earth, in which case they reflect the light of the sun to observers on the earth who are in favoured relation to them. Moreover, it may well be that the magnetism of the earth would tend to concentrate such iron particles, if any, in the space around it. If we have found a clue to the observed effects, further observations and investigations may confirm or oppose the hypothesis presented.

Lynn, Mass, Sept. 1.

#### The Fields of Force in the Atmosphere of the Sun.

While appreciating M. Deslandres's concluding paragraph of his letter in Nature of Oct. 8, and reverting first to the problem of the equal spacing of magnetic disturbances, synchronous with corresponding spacing of solar longitudes, I am afraid my studies, to which he kindly alludes in Comptes rendus for Sept. 1926, came to a stop for reasons of the statistical material I up to then could work upon, failing me. Nor can I dispose of the required magnetic recording apparatus of the kind used at Meudon, and I was wholly confined to the Greenwich spot records, and to my own observations of eruptive phenomena either at the limb or on the disc. The first diagrammatic representation of this phenomenon which I made covers the minimum period, section from July 1913

to Dec. 31, 1914, and I found that my method for a maximum activity period resulted in great diagrammatic complication, not to say confusion. All the same, I felt from the first convinced that I was by no means dealing with an accidental phenomenon, and I am therefore very hopeful that the method used at Meudon will ultimately be completely successful.

M. Deslandres's proposition of an interior solar sphere, rotating like a solid, is very fascinating, and has, as an a priori assumption, many points of merit, but on the other hand also raises other difficulties. One of these is how to reconcile the equatorial acceleration with a deeper seated level, which rotates with equal angular speed in all latitudes. What becomes of the striking independence of activity for the two hemispheres, when for months at a stretch scarcely a spot, or a substantial prominence, appears in the north, or in the south? Certainly the observational fact remains, that pronounced activity may be confined for long periods within a very limited range of longitude and latitude; but even then great variations occur, which seem to preclude the idea of stationary eruptive, even intermittently eruptive, volcanoes. Diagrams I have made, covering many years, show these latitude changes for successive rotations perfectly plainly. At Stonyhurst they carry on a method of tabulation, which shows the changes in longitude and latitude on the same diagram. M. Deslandres offer a physical explanation of these changes, retaining the interior sphere which in his opinion gives birth to the solar spot and rotates as a solid would?

M. Deslandres refers to the difficulty of explaining the much lower temperature of solar spots. Nothing has occurred since I began to observe the sun thirty years ago, which upset my initial conviction that the evidence of the spectroscope in this respect is misleading. It should be remembered that when examining the sunspot spectrum, we allow combined light to pass mto the instrument, not only that radiated by the spot-umbra and lower down, but also from great altitudes above the spot, all in the direct line of sight. Now my contention is that heaped up above the spotumbra and its vicinity there are the gases of the uppermost and coolest layers of the sun's atmosphere, as in fact the photographic representations of the solar vortices intimate. These photographs receive their 'design' from the dark absorptively acting filaments at great altitude, converging and descending towards the spot in precisely the same way as the cloud trunk does in the terrestrial tornado, or in the waterspout phenomenon. The trunk of the solar tornado can be seen directly in many cases of active solar spots and gives rise to the 'claw' effect so well illustrated in W. C. D. Whetham's book, "The Recent Development of Physical Science," but the spectroscopic explanation is erroneous, as given on page 308. All this points directly to the screening from the terrestrial observer of the umbral level by a concentration of relatively cool gaseous masses above the spot. I have yet to see the observational, or physical, refutation of the late Mr Wilson's temperature measurements of solar spots carried on at Daramona in 1895, which indicated the spot radiation at the limb to be relatively higher than when the spots were central. I submit that if M. Deslandres dismisses the theory of sunspots being cooler than their surroundings, at the level of the photosphere, he will find several problems easier of comprehension and explanation.

Nor do many phenomena in connexion with prominences admit of the dogma, that the sun is a truly gaseous body. Such types of eruptive prominences as the fascinating, clean-cut parabolic jets, are irreconcilable with a genuine gaseous state, and point

at best to a quasi-gaseous-cum-quasi-liquid interior

The magnetic field seems to me to be induced mechanically by the whirling vortex, and I have seen on more than one occasion on the sun's limb an exact and complete representation of the converging luminous  $H_{\alpha}$  filaments, as represented in Dr. Stormer's theoretical diagram, page 31, No. 109, of the Mount Wilson Contributions, these luminous lines strikingly representing the magnetic lines of The creation of a magnetic field about sunspots by the vortex appears to me a direct result of the violent temperature changes which are going on Thus, for example, the conduction of hot steam into cool water means abrupt condensation and is accompanied by strong electric effects, particularly noticeable when the vessel containing the cool water is fairly well insulated. I have often wondered why this simple experiment has not been followed up and made use of industrially. Once electric effects are admitted in connexion with, and due to violent temperature changes, it does not appear very difficult to understand the possibility of attraction and repulsion effects also. ALBERT ALFRED BUSS.

#### Flame and Combustion.

As a result of investigations on the effect of 'antiknock' compounds on the ignition of hydrocarbons, it was concluded that the combustion of hydrocarbons was autocatalytic and that the 'antiknocks' delayed oxidation by destroying the catalyst. It was further pointed out that these processes of catalysis were connected with the peroxidation of the fuel and of the antiknock, and that the course of the catalysis depended on the oxygen concentration (Jour. Inst

Pet. Tech., pp. 244-280, 1927).
The effect of carbon disulphide on ether-air mixtures (cited by Dr. White in NATURE of Jan. 8, 1927), its effect also in raising the igniting temperature of petrol and in preventing 'knock' in engines in spite of its inflammability, can be ascribed to similar actions. Sulphur (particularly if combined with a reducing radical) can act as an 'antiknock' in the same manner

as selenium, though to a less degree.

One is led to expect that the effect of water and of hydrogen on the combustion of carbon monoxide—air mixtures would be a similar case of catalysis, in which the peroxidation would be influenced by 'antiknock' compounds. The first experiments made to test this point were unsuccessful; Mr. Gates and I found that lead tetraethyl did not influence the combustion of carbon monoxide—hydrogen—air mixtures (except sometimes, it seemed, in explosions of a vibratory character). It was thought that the lead tetraethyl vapour probably did not have time to be decomposed before reaching the zone of combustion and could therefore not modify the flame speed. This surmise appears to be correct; Mr. Goodey and I have found that iron carbonyl, which decomposes at a lower temperature than lead tetraethyl, modifies the combustion of carbon monoxide—hydrogen—air mixtures very considerably.

The object of this letter is to direct attention to the importance of the study of the stages of combustion which precede inflammation—an importance to which Prof. Bone, from another point of view, has directed attention by his recent work on the explosion of methane—oxygen mixtures (Proc. Roy. Soc., 114, p. 442; 1927). The process which goes on in the body of the gas is catalytic and has a great influence on the subsequent ignition of the mixture, and is even important in the narrow region of heated gas immediately in front of an advancing flame. A EGERTON.

Clarendon Laboratory, Oxford.

In conjunction with Mr. D. L. Hodge, for some time past I have been studying experimentally the combustion of  $2CO + O_2$  (moist and dry) in a steady high tension direct current discharge, and the experiments have resulted in some new observations which seem to have an important bearing upon the function of steam in the combustion of carbonic oxide. soon to communicate a detailed account of them to the Royal Society; meanwhile, in view of the general interest in the subject, we should like to make the

following brief statement of the results

In such a high tension direct current discharge, combustion may be wholly localised either (a) at the cathode or (b) in both the cathode and the positive column zones. By the methods which we have employed, we have been able to study the influence of moisture on both the cathodic and the positive column combustion. Our results have shown that in the cathode zone, where the fall of potential is very steep and the ionisation accordingly intense, the rate of combustion is quite independent either of the gas pressure or of the presence of moisture, but is proportional to the current passing, that is, to the number of ions arriving at the cathode per unit of time. In this region, the presence of moisture, so far from assisting combustion, slightly hinders it, owing to its diluent effect. Thus a sulphuric acid - dried 2CO + O2 mixture combined in this region at a rate about 15 per cent. faster than did the same mixture when saturated with water vapour at 17° C.

In the positive column region, however, where the potential gradient is slight as compared with that of the cathode zone, the presence of moisture greatly

accelerated the combustion.

It would thus appear that, whereas moisture may accelerate combustion in a  $2\text{CO} + \text{O}_2$  mixture in a region of comparatively weak ionisation, it has no influence, other than that of a diluent, in a region of sufficiently intense ionisation. Such results confirm the conclusions already drawn by Prof. Bone from his experiments, namely, that moisture is not essential to the combustion of carbonic oxide, and that (in cases where it accelerates the process) its rôle is electrical G. I. Finch. and not chemical.

Department of Chemical Technology, Imperial College of Science and Technology, London, S.W.7.

In commenting upon our previous letter in Nature, Oct. 22, Prof. Armstrong stated that, in comparing the heats of combustion of carbonic oxide and hydrogen in flames, he had taken into account the keat of formation of water, not that of hydrone (steam), which can only mean that he supposes water (not steam) to be formed in flames. This being so, will he then kindly vouchsafe us an answer to the question put to him in our letter, namely: Is there, indeed, any evidence that not 'hydrone' (steam) but something much more complex and 'hydronolic' (water) is formed in flames? For we want to know what his answer is before deciding whether or not it would be safe for us to accept (as he suggests) the guidance of his 'imagination' whilst wearing our 'thinking caps.'

#### Absorption of X-Rays in Various Elements.

Recent investigations of the absorption of X-rays m different elements (aluminum, nickel, copper, silver, and platinum) and extended over a great region of wave-lengths (0 7 to 12 A.), using strictly monochromatic radiation, have led me to the following general laws:

1. The jump  $\delta_K$  of the absorption coefficient on passing the K-absorption limit is:

$$\delta_K = E_K/E_{L_1},$$

where  $E_K$  and  $E_{L_{\rm I}}$  are the energy-levels corresponding to the K- and  $L_{r}$ -levels respectively (see Siegbahn's "Spectroscopy of X-Rays," pp. 184-185). The total jumps at the L- and M-absorption limits are in the same way determined by the formulæ:

$$\delta_L = E_{L_I}/E_{M_I}$$
 and  $\delta_M = E_{M_I}/E_{N_I}$ .

2. If the absorption is calculated per electron  $\mu_{\epsilon}$ 

instead of per mass unit  $\mu/\rho$  ( $\mu_{\epsilon} = \frac{\mu}{\rho} \cdot \frac{M}{N \cdot L}$ ; M is the

atomic weight of the absorbing element, N its atomic number, and L the Loschmidt-number), it can be shown from my own measurements and from earlier investigations that  $\mu_{\epsilon}$  is a function of the product  $N\lambda$  for every branch of the absorption curve.

3. By using these two laws it is possible to give in a diagram, with  $\mu_{\rm e}$  and N\Lambda as co-ordinates, one single continuous curve for the absorption at all wavelengths and for all elements.

The new measurements and the results here mentioned will be given in a doctor's thesis (now in print) at the University of Upsala.

Edvin Jönsson.

#### The Electric Arc in High Vacuum.

WITH reference to the interesting letter by S. Ratner on the electric arc in high vacuum, published in NATURE of Oct. 15, p. 548, this type of arc has been observed previously by me under conditions very similar to those used by the author (see *Phil. Mag.*, vol 2, p. 796; 1926). I found that it could be excited in residual gases or in hydrogen at very low pressures, provided that an initial electrical discharge was sent between one of the iron electrodes and a

The radiation emitted showed no trace of the iron lines, but gave a bright continuous spectrum together with lines and bands from the various gases present. There were really two types of arc-the ordinary arc, where the current rose in some cases above 10 amperes, and a brilliant glow during which a small current passed between the electrodes. Both these types could be excited at such low pressures that there was no trace of luminosity due to the electrical discharge.

Such an intermittent are would form a convenient type of relay if the initial electrical discharge required were feeble, and if the arc would strike each time that this feeble discharge was sent through the tube. It was found, however, that these conditions were not fulfilled, the state of the electrode surface being an important factor.

The phenomenon is very interesting, and considering that the electrodes are cold, there seems to be no satisfactory explanation. F. H. NEWMAN.

University College, Exeter.

Psychological Dissociation as a Biological Process.

In "Instinct and the Unconscious" the late W. H. R. Rivers suggested that the mechanisms of psychological dissociation familiar in human psychopathology have played a large part in the adjustment of the behaviour of animals during metamorphosis and in other changes of environment. The subject clearly had a great fascination for Rivers, and he reverted to it in a later paper ("Psychological Dissociation as a Biological Process," Scientia, vol. 35, p. 331; 1924). The purpose of this letter is to direct attention to the significance of a discovery which goes far to confirm these speculations.

In a recent paper on "Loss of Memory accom-

panying Metamorphosis in Amphilia "(P.Z.S., pt. 1, p. 155; 1927), Major S. S. Flower records that salamander larvæ tamed to feed from the hand lost all their tameness at metamorphosis and had to be trained again de novo. In the main this abrupt disappearance of larval behaviour is just what Rivers predicted, though it appears to be correlated with the internal rather than the environmental changes of metamorphosis, the salamanders being apparently still partially aquatic when the change occurred.

It is much to be hoped that Major Flowers' most interesting observations will be extended and amplified. One would like to know, for example, if premetamorphic training facilitates or prejudices the acquirement of the behaviour after metamorphosis. Some quantitatively observable conditioned reflex would be invaluable in the investigation.

In conclusion, it may be emphasised that the abrupt change corresponds more to repression (= suppression of Rivers) than to gradual growth out of a childish habit, and suggests that the former is, as Rivers suggested, a normal biological process not as Kivers suggested, \_ \_ confined to human pathology.

#### Geological Survey of Uganda.

An unfortunate error has crept into the Annual Report of the Geological Survey of Uganda for the year 1926, whereby the reader is informed that Mr. A. D. Combe, of this Survey, is of opinion that there is a continuous succession through the Transvaal System into the Waterberg System in the Cape Province of South Africa. May I be permitted to make use of the columns of NATURE to correct this error? Perhaps readers of this journal who have copies of the report will kindly turn up page 32, delete line 34 and delete all of line 35 except the last

word and the comma in front of it, and re-write thus: "Mr. Combe suggests that in the Katanga Province there may be a continuous conformable succession through the equivalents of the Transvaal and Waterberg Systems without an unconformity, similar to the grand conformable succession, in parts of the Cape Province, through the Cape and Karroo WILLIAM C. SIMMONS. Systems."

# Green Lightning.

DURING a thunderstorm last night, a flash of lightning started from the top white, and about half-way down turned to a vivid green. Possibly I am very unobservant, but I do not remember ever to have seen green lightning before. Y.M.C.A., H. H. STEPHENSON.

Brantford, Ontario, Oct. 7.

# The Germplasm and its Architecture.1

By Dr. F. A. E. CREW.

THE individuals of a generation die, but life is transmitted to its successor through the exercise of the function of reproduction handing on of the torch of life, in the more highly organised forms, consists in the union of the gametes, egg and sperm, to form the zygote, the new individual and the next generation, specific to the highest degree and embodying all the possibilities of individual development and of racial perpetuation. Each of the sexually distinct parents contributes but a single cell, so minute as to be far beyond the limits of the unaided eye, yet these gametes are the only material link between the generations, and across this, the narrowest of bridges, everything organic that one generation can receive from its predecessor must pass. The zygote exhibits none of these details of structure and of function which, when the individual has assumed its definitive form, will enable the observer to describe and to classify it, yet in this fertilised egg there must surely be something that predetermines much of the individual's future morphological, physiological, and psychological limitations.

That offspring do in general resemble their parents is so familiar a fact that its significance is either overlooked or over-emphasised. It has been accepted, without wonderment, that a multitude of characters is faithfully transmitted from generation to generation; that like tends to beget like; that it can be predicted confidently that every individual conceived will sooner or later exhibit those details of form and of function which characterise the species. the race, even the family to which it and its relatives belong. The doctrine of homogenesis still satisfies the biologist. It has equally long been recognised that no son is the 'carbon copy' of his father, that each individual is the first and the last of its identical kind; that indeed variation is universal. It may be assumed that out of accumulated anecdotes concerning the similarities and dissimilarities in characterisation exhibited by related individuals, there soon arose the notion that in their distribution there were suggestions of an orderliness, a regularity, that many characters were indeed being inherited and that the mode of their inheritance was not a haphazard affair but was surely subject to certain rules. Thus it would soon become inevitable that the human mind, in its inherent desire to trace and to describe order in Nature, should seek some mechanism which in its functioning could account for this observed orderliness. A consideration of the observed facts of organic inheritance enabled man to form a general theory of inheritance, a speculative thought-model of what the architecture of the hereditary material might be.

The question to be answered was, "How is it that like begets like?" In the latter half of the eighteenth century it was customary to appeal to

vires formativae, hereditary principles, hereditary tendencies, by the aid of which the seed grew into the likeness of its parents. In an age when materialism was not gross and when the microscope was most imperfect, it was inevitable that scientific men should resort to merely verbal explanations, which at best were gestures of respectful ignorance and of admiration. But improvements in techniques and additions to knowledge quickly eroded

such purely metaphysical hypotheses.

During the seventeenth, eighteenth, and the earlier part of the nineteenth centuries, the most favoured explanation of the facts of inheritance and of development was some form of the theory of preformation and evolution According to this, the egg, or the sperm, contained within it a perfect but miniature model of its parent, preformed though invisible, which required only to become unfolded, evolved, in order to reveal itself. This theory of ontogeny was extended to include phylogeny also, and it was taught that within this miniature was a second, and within this a third, and so on in increasing numbers until all the future generations were supplied; within mother Eve it was estimated were some two hundred thousand million homunculi, one within the other, like the components of an infinite juggler's box of which there is no end. Ovist and animalculist debated violently, yet both were agreed in this, nothing was generated, and what was thought to be generation was but merely the enlargement of that which had pre-existed in an invisible form. Haller it was who declaimed, "Es gibt kein Werden"—there is no becoming—and the theory held sway until it staggered under the blows of Wolff's demonstration of the gradual development of the apparently simple into the manifestly complex. Wolff demonstrated that development was epigenetic, taking the form of a true series of transformations, and was not merely the enlargement of what previously had been invisible.

Just, however, as the preformatists could not easily account for the origin of their miniatures, so Wolff was unable to explain the demonstrated fact that the end-result of epigenetic development was an individual similar in characterisation to its parents, save by an appeal to the aid of a vis corporis essentialis by which the plastic organic material controlled its own destiny. Wolff was not unique in this; it has ever required the severest intellectual ascetism to banish from the scientific mind this tendency to explain by an appeal to a metaphysical conception, and since his time this inherent force has been recreated by many who have been at pains to give it another name; purposive striving, emergent evolution, creative evolution, are examples, for man ever creates his gods and imprisons them in the machines that he invents.

These theories in their sequence were signposts along the road we are travelling, for out of them emerged the firm conviction that the future in-

No. 3028, Vol. 1201

 $<sup>^{\</sup>rm 1}$  Evening discourse delivered at the Leeds meeting of the British Association on Sept. 5.

dividual must be materially implicit in the gamete. and that not only did this single cell contain the rudiment of the next generation but also those of all succeeding generations as well. Soon the conception arose that the germ-cells were distinct from the rest of the body; that they were to be looked upon as centres of contributions from the different parts of the body. The central problem of heredity came to be that which was concerned with the manner in which the various heritable qualities of the individual got into the germ-cells produced by that individual Theories of pangenesis, which had flourished from the time of Democritus, were revived and extended but soon gave ground as the conception of germinal continuity, finding support in the newer facts of It had been shown cytology, gripped the mind that in certain instances it was possible to dis-tinguish between those cells of the segmenting zygote which were destined to become the reproductive organs and those which were to become the body of the individual. The distinction between the ontogenetic and the phylogenetic became more and more emphasised as time went on, and soon it became evident that in the fact of material continuity between the reproductive elements of generations must be found the solution of the problem as to how it is that like tends to beget lıke.

To Weismann is mainly due this replacement of pangenetic theories by genetic. He taught that the germ-cells were to be regarded merely as parts of an unbroken line of germplasm, the bearer of the heritable qualities; that this germplasm, in certain circumstances, usually the union of two of its constituent germ-cells, frothed up and produced a great excrescence, the somatoplasm, the body of the next generation, and continued its existence therein, that the germplasm was immortal, the body mortal; that the germplasm had existed from the very dawn of life, whereas the body was formed afresh in every generation, that when the zygote divided, some of the resulting cells were set apart at once and took no further part in the building of the body, but remained, later to become the germ-cells of the individual

Weismann postulated that what is actually continuous is the germplasm of definite chemical and specific molecular constitution, that a continuity of actual germ-cells is rare, but that a continuity of intact germplasm is the rule. According to such a genetic theory of inheritance, an individual is like its parents, not because it is produced by them but because both parent and offspring are produced from the same stock of germplasm. The somato-plasms of father and son are developments at different times from one and the same continuous stream of germplasm. Organic inheritance, all that the individual possesses in virtue of the hereditary relationship, implies a rhythmical repetition of a definite, and on the whole, similarly repeated series of events leading to the production of an individual which liberates germ-cells capable of initiating the same process.

The problem of organic inheritance thus became

restated. It was now concerned with the manner in which the heritable qualities of an individual were represented in the germ-cells which in their union produced the individual; the need for critical experimental investigation of the problem of heredity and variation was recognised and the stage was set for the re-entry of Mendel. When the records of his work of some forty years before were brought to light in 1900, it was recognised that in them was confirmation and extension of the essentials of Weismann's hypothesis, but that no longer was it necessary to invoke a hypothetical mechanism for the distribution of the hereditary factors, for by this time independent cytological investigation was disclosing a satisfactory mechanism within the living cell.

Mendel had taken for his problem the question as to the exact manner in which the definite and true-breeding varieties within a species are related one to the other. He considered the individual not as a unit in inheritance, but concentrated his attention upon the mode of inheritance of pairs of sharply contrasted characters. The method he adopted was that of hybridisation, and he kept accurate pedigree records showing the ancestry and the characterisation of each individual. He counted the number of individuals in each generation and the numbers of dissimilar kinds, and was able to give an exact mathematical statement of his results. His was the first attempt to reduce the phenomena of inheritance to a measurable basis, for he employed the exact quantitative methods that scientific discipline demands. The man, the method, and the material made discovery certain. He found that in the case of every one of the seven pairs of contrasted characters of the culinary pea with which he dealt, the mode of inheritance was the same. Out of his experimentation there emerged clearly the verifiable fact that when one or more pairs of alternative characters are involved in a breeding experiment, there is in the second hybrid generation an orderly reappearance of these characters in definite numerical proportions.

Mendelism is a scientific theory relating to the distributive mechanism of organic inheritance which, like most other hypotheses of this kind, postulates the existence of a number of individual particles of substance-factors—in the germplasm each of which in its action influences the development of some particular character. It does not require that these particles shall be concerned solely with hereditary transmission. It demands that in respect of any particular character the individual must receive from its parents, one from each by way of the gamete, two factors, either similar or dissimilar according to whether or not in the respect of this character the parents were alike or different. It requires that when the individual in its turn elaborates its reproductive cells, into each ripe gamete there shall pass one or other, but not both, The gamete can contain but a of these factors single set of factors; the zygote a double set, and of these one set shall have been received from each parent. Thus the zygote may be hybrid in respect of a character or characters since one or more pairs of factors in its constitution may consist of dissimilar mates: the gamete, on the other hand, cannot be hybrid, since factorially it is constitutionally simplex. The theory postulates that the association of dissimilar factors in the zygote is not attended by any adulteration effect upon them.

The Mendelian method of character analysis, ardently pursued during the first decade of the twentieth century, made it perfectly clear that if there were actually such a thing as a material basis of organic inheritance, if the germplasm did exist in fact, then in the cell there must be some unit which is structurally continuous through all cell divisions from the first cleavage of the fertilised egg to the liberation of the ripe gametes by the resulting individual; that these units must be present in duplicate in the zygote; that they must segregate into single components at some point before the functional gametes are finally formed, and that in the zygote these units must be present in pairs.

As was to be expected, it was not long before results were obtained from breeding experimentation which demanded extension and modification of the theory as originally promulgated by Mendel Mendel's second law of the independent segregation and recombination of factors, for example, was found by Bateson and Punnett not to apply invariably. In several instances this free assortment was found to be more or less absent, and characters in their transmission from generation to generation exhibited the tendency to remain together. In appropriate matings and in those cases in which such linkage was evidenced, linkage

proved to be incomplete and the percentage of recombination classes was found to be constant under controlled and stable conditions of experimentation and to be characteristic of a particular mating. With greater experience came the power to predict the percentage of such recombination classes in any experiment involving characters which exhibited this linkage relationship and such prophecy has been abundantly verified, and no exceptions so far have occurred to the rule. Upon this general result the hypothesis of the linear arrangement of factors within the germplasm is based.

As a result of this more recent experimentation, the factorial theory of organic inheritance has become modified and greater have become the demands which must be made upon the germplasm. It is now generally accepted that the hereditary characters are referable to paired elements in the germplasm which are held together in a definite number of linkage groups; that the members of each pair of elements separate when the germ-cells mature, in accordance with Mendel's first law, and in consequence each gamete comes to contain one set only; that the members of different linkage groups assort independently, in accordance with Mendel's second law; that an orderly interchange—crossing-over—takes place at times between the elements in corresponding linkage groups; and that the frequency of crossingover furnishes evidence of the linear order of the elements with respect one to another. The germplasm in its nature and architecture is now required to be such as can accommodate the facts of linkage, of crossing-over, and of the linear order of factors. (To be continued.)

# Standards of Performance of Heat Engines.

THE discovery of the interchangeability of heat and mechanical work has been followed by and mechanical work has been followed by progressive efforts to attain the maximum ratio for the efficiency of conversion of the former into the latter. It is significant of the limitations which attach to such conversion, and the remoteness of a complete solution, that after a century of progress we are still striving to express this efficiency as the ratio of a ratio. This reflection is suggested on perusal of the report recently issued by the Committee of Heat Engine Trials under the auspices of the Institution of Civil Engineers, one of the objects of which is to determine a suitable standard of performance, which shall have a known efficiency ratio, and to express the actual performance of an engine as a ratio thereof.

The limitations are well recognised. There are first of all those of a thermodynamic nature, which prescribe that within given limits of temperature the defect from perfect conversion cannot be less than the ratio of the minimum to the maximum absolute temperature; in other words, the maximum possible efficiency is given by  $(1 - T_2/T_1)$ ; this is known as the Carnot efficiency, belonging to a perfect heat engine working on such a cycle that

heat reception takes place at, and only at, the maximum temperature  $T_1$ , and heat rejection solely at the minimum temperature  $T_2$ 

at the minimum temperature  $T_2$ It might be thought at first that the quest for an intermediate ideal could end here and that this simple expression for the maximum efficiency thermodynamically possible would answer the requirements. But there are further limitations of a practical nature on account of which the Carnot efficiency ratio is still a long way removed preferred what can be obtained in practice, and it is pring a lower to soothe our baffled ambition by add at can actually be realised.

The nearest approach to the Csci g saturated steam. In the steam engine when usin at the feed water up the feed to boiler temperature, the verteeption takes place at a corresponding to the heat temperature, and, if we assume no losses by a condenser temperature. This this known as the condenser temperature. This this known as the carnot cycle. The only defined from the carnot cycle is in the replacement cess of elevating pression stage by the simpler protes.

the condensed water to boiler pressure in the feed The consequent almost complete elimination of negative work gives the Rankine cycle a great practical superiority, and the early success of the steam engine as a prime mover was largely due to its ability to work on this cycle with saturated

The Rankine cycle was therefore considered a more suitable standard of comparison than the Carnot cycle, and came into general employment by makers and users of reciprocating engines. It was adopted as the criterion of performance by the first Committee on Heat Engine Trials in 1898, and reaffirmed by the Committee of 1903-1905. The processes of the Rankine steam cycle are (1) reception of heat at constant pressure, (2) adiabatic expansion, (3) rejection of heat at a constant pressure and temperature, (4) restoration of the feed water to boiler pressure

With the adoption of superheated steam, an extension of the cycle was necessary, to include the superheating process, but since, when employing superheat, evaporation takes place at a temperature below the maximum of the cycle, the Rankine cycle becomes further removed from the Carnot cycle, in the sense that it does not follow the latter to the full realisation of the increase of efficiency made possible by the higher maximum

temperature.

In later practice it has become customary to speak of the Rankine cycle as though it were synonymous with a modified cycle in which the volume of the feed water is neglected, the work done in the cycle being then equal to what is known as the 'available energy' of the steam between its conditions at admission to, and exhaust from, the engine. As a standard of measurement of the efficiency of the engine itself there is much to be said for it, and the development of the turbine has familiarised us with the conception of an engine steadily extracting from the steam its available

Finally, the properties of steam have now been so thoroughly explored and reduced to a thermodynamically consistent basis, that it is a comparatively simple matter to calculate the available energy of the steam even under complicated conditions of supply such as are entailed by the modern practice of bleeding steam from turbines to heat the feed water, and of reheating the steam at intermediate stages of its expansion. The Committee, which has just issued its report, has accordingly recommended referring the performance of the engine to the available energy in the steam according to the conditions of its utilisation, which energy can be calculated by well-known

While this serves excellently for the appraisement of the engine performance, it must not be overlooked that attention has been diverted from the heat engine proper and confined to that part of it only which carries out the process of expan-The heat input as evaluated in the report is also different from the heat input of the Rankine cycle, in that it includes the small

amount of 'total heat' put into the feed water by the feed pump. The efficiency thus calculated for the standard of performance is no longer that of the Rankine cycle heat engine.1 For moderate pressures the differences are small, but they become appreciable when high steam pressures are employed.

A similar approximation is not possible for the internal combustion engine, since in this case the negative work is considerable It results that the difficulty of finding a satisfactory standard is increased. The Committee has re-affirmed the conclusions of the Committee of 1903, which recommended the adoption of the air-engine standard, namely, an engine working with a perfect gas of the same density as air and operated between the same maximum and minimum volumes as the actual engine. This recommendation of the earlier Committee was qualified by the admission that amendment might be required later on the acquisition of more accurate data regarding the variation of specific heat with temperature.2 Sir Dugald Clerk has pointed out that the practical thermal efficiencies are of the order of 70 per cent. of the air standard efficiency for most economical mixtures, and a note in the new report discusses the effect of variable specific heat upon the efficiency of the air cycle, giving curves for various types of engine. The correction factors so introduced are considerable and vary with the heat input, that is to say, with the mixture strength of the actual engine and also with the type of engine.

The Report recently issued is, however, a veritable mine of information. In addition to the discussion of the thermodynamics of the subject in the introductory notes, forms of record are given making available to users of heat engines and to research workers authoritative methods of recording and reducing the results of efficiency and capacity trials. The Report takes within its scope boilers and steam engines for land and marine purposes, gas producers, gas engines. heavy oil engines, and petrol or paraffin engines. Schedules are presented for each section indicating in comprehensive detail the various measurements to be made, each leading up to a heat balance account for the plant under test. The value of these schedules is enhanced by copious notes for the guidance of the engineer

employing them.

A valuable addition to the Report is a series of appendices, dealing with instruments and methods for the most important of the measurements that In virtue of all this additional are required matter, this Report on the tabulation of engine trials has been elevated to the rank of a text-book of the subject, and a useful work of reference.

<sup>1</sup> If H', H'' be the total heat at beginning and end of adiabatic expansion, h' the total heat of water at condenser temperature and pressure, standard efficiency ratio as adopted  $= \frac{H' - H''}{H' - h'}$ , efficiency of Rankine cycle  $=\frac{H'-H''-w}{H'-k'-w}$ , w being work (in heat units) of the feed pump See Callendar, "Properties of Steam," p 219

# Rothamsted Experiments.1

PERIODIC summary on the work at the Rothamsted Experimental Station is an essential if teachers and others are to keep in touch with its activities. Its place is between the fleeting impressions of a summer-day visit, and the detailed monographs and specialised publications. This is recognised in the preparation of the report, and one can obtain in brief the more outstanding results, in this case for the years 1925 and 1926. If the critic sometimes feels that 'research in agriculture' is merely a phrase, he will find that it is a reality at Rothamsted.

The many-sided activities of the station of to-day are at once apparent from the staff-list, and one recalls the few workers and the meagre equipment of the Rothamsted of Lawes, Gilbert, and Warington. Yet even then the reputation was being made that now attracts temporary workers from all parts of the world. The large proportion of biological workers is noteworthy as evidence of the recognition of a living plant and a soil where organisms play an important part. There has also been an increase in the departments concerned with statistics and conducting of field experiments. The activity of the director and the staff is evident from the number of papers published, and the student struggling to keep pace with the present large output of agricultural literature will be grateful for the terse summaries of the more strictly scientific papers, extending to thirty pages of this report. Another direction in which the station has done valuable work is in organising conferences, which have been of the nature of symposia on particular aspects of agricultural science, or meetings of farmers with the staff and other scientific workers for the discussion of recent developments and their significance in agricultural practice. Then there are the extra-mural activities, such as organising displays for the Royal Agricultural Show and other exhibitions, and the work of the guide lecturer, who demonstrates the station's work to visitors and, during the winter months, delivers lectures to farmers' and other institutions on agricultural topics

The key-note of the earlier Rothamsted work may be described as propaganda on the use of fertilisers, but as these are now incorporated as part of ordinary farm practice, modern problems are concerned with details that are factors of prime importance in crop production The sixty-year experiments are still continued, but are amplified by being repeated in other parts of the country, and through more exact observations on the crop-plants. Thus it is no longer the work of a research station to persuade farmers to use artificial manures, but it is still a problem how to get the best value out of the manures. There seems to be good evidence that at Rothamsted and elsewhere I cwt. of sulphate of ammonia may be expected to give an increase of 20 cwt. in the case of potatoes, and 4 cwt. or 8 bushels for barley. The results for phosphates and potash are

not so regular, although the fertility of the soil will almost certainly decrease if these are not maintained.

The interaction of one manure with another is also being investigated. In recent years increased attention has been given to minerals not actually plant nutrients, but influencing growth; boron, silicon, and manganese have been subjects of recent papers. Experiments on chlorides show that muriate of ammonia raises the yield of barley, not by increasing the numbers of ears but by improving the yield of grains per ear, in other words, chlorides appear to increase the movement of food materials towards the grain. The nitrogen content of barley, so important in malting, has also been under experiment, and results are given.

Since 1921 sheep-grazing has been included in the programme, thus supplementing the original manuring of grassland plots where the results were limited in application because they were investigated for Grazing complicates the problem, hay yield only and the period of these experiments has been too short to allow of conclusive results There is evidence that the amount of soluble phosphates in slag is only a rough measure of its utility. Results bear out the recognised fact that good land does not show so much response as poor land, or as the report puts it: "Grassland is not readily improved by slag if an acre of it yields some 200 lbs. live weight mcrease in sheep; the striking results are obtained on land giving only 50 or less lbs. increase per acre "

Methods of field experimentation are being intensively studied, as shown by the number of publications dealing with these or including them in arriving at results. A new departure is the staff and field laboratory for making measurements on the growing plant, since it has been found that in this way more useful information is obtained than by using weighings at the end of the experiment alone. The figures obtained are now handled by the statistical staff to estimate error, etc. Reasons are given for the adoption of 'standard error' (p. 122), and the merits of 'the Latin square' and randomised blocks' are discussed (p. 28). The soil physics department indicates its attempts to amplify the empirical rules of cultivation into a science. The studies on soil resistance as measured by the dynamometer, are illustrated by a diagram of Stackyard field showing the easing in plough-pull after 'chalking'. Other problems bear on soil texture as distinct from chemical properties

Soil microbiology, another recent development, is briefly explained, including some applications in practice, namely, inoculation of legummous crops, partial sterilisation of soils, and fermentation of cellulosic materials to produce artificial farm-yard manure. Other departments are concerned with losses of crops, including studies on what is involved in the resistance of so-called immune varieties. Altogether the report is not merely informative, but is also strongly suggestive of possible lines for demonstration and research, hence it should be in the hands of all interested in the principles and practice of agriculture.

#### News and Views.

THE following awards have been made by the president and council of the Royal Society, and the King has approved the awards of the Royal Medals: The Copley Medal to Sir Charles Sherrington for his distinguished work on neurology; a Royal Medal to Sir Thomas Lewis for his researches on the vascular system, following upon his earlier work on the mammalian heart-beat; a Royal Medal to Prof. J. C. McLennan for his researches in spectroscopy and atomic physics; the Davy Medal to Prof A. A. Noves for his work in physical chemistry, especially on the subject of electrolytic solutions, the Buchanan Medal to Dr. Major Greenwood for his statistical researches and other work in relation to public health; the Hughes Medal to Mr W D Coolidge for his work on the X-rays and the development of highly efficient apparatus for their production.

AT the meeting of the Royal Society on Nov. 3, Mr. Stanley Baldwin was elected a fellow of the Society under Statute XII., which provides for the election of persons who "have rendered conspicuous service to the cause of science, or are such that their election would be of signal benefit to the Society." The following is a list of those recommended by the president and council of the Society for election to the council at the anniversary meeting on Nov. 30:-President, Sir Ernest Rutherford; Treasurer, Sir David Prain; Secretarics, Mr. J. H. Jeans and Dr. H. H. Dale, Foreign Secretary, Sir Richard Glazebrook; Other Members of Council, Dr. E. D. Adrian, Sir Hugh Anderson, Dr. F W. Aston, Dr. F. A. Bather, Sir Archibald Garrod, Sir Thomas Heath, Prof. A. Lapworth, Prof. J. C. G. Ledingham, Prof. F. A. Lindemann, Mr. J E. Littlewood, Mr. C. Tate Regan, Prof. A. C. Seward, Prof. G. Elliot Smith, Dr. T. E. Stanton, Sir Gilbert Walker, Sir James Walker.

THE Gallie race can boast of a long list of front rank and even alliterative mathematicians-Laplace, Lagrange, Legendre, Picard, Poincaré, Painlevé, to mention only a few—but M. Paul Pamlevé provides that rare combination of mathematical and political emmence that is almost without parallel. While the subject with which he will deal on Nov. 15 in his address at the Royal Institution on "Les conceptions modernes de la matière et de la science classique "will be primarily physical and philosophical, his mathematical energies have been devoted mainly to the purer aspects of that subject, although not exclusively so. Thus in his paper in the Bulletin Astronomique (1898) he made important contributions to the problem of three bodies, but the focus of his work has primarily been differential equations and the theory One of his earliest papers on the of functions singularities of functions, "Sur les lignes singulières des fonctions analytiques" (Comptes rendus, 1887), enunciates a number of important theorems relating to the continuity of the boundary values assignable to Dirichelet's problem. He extended the conception of the Schwarzian derivative to differential equations

of the third order, deriving the invariants and indicating the procedure to be adopted towards solution. In his crowned memoir, "Sui les équations différentielles du premier ordre" (1891), he propounded the theorem named after him that the points of indeterminateness, and in particular the essential singularities of the integral of an equation, are fixed points determined by the equation itself.

PAINLEVÉ'S Stockholm Lectures (1897), largely based on the theory of rational transformation of curves and surfaces, contain some of his best work treat of the analytical theory of differential equations and examine the descriptive properties of the in-Many of his later memoirs in the Comptes rendus deal directly with various problems in Function Theory—functions with unlimited essential singularities and expansions in series. As an extension of the theory of continuation he showed how to construct a single expression in the form of an infinite series of polynomials which would be a valid representation of a function over an extended domain. It is perhaps no exaggeration to say that much of the classical treatment of differential equations might never have been written were it not for Painlevé's investigations on that subject and on the theory of functions. In addition to his lecture at the Royal Institution on Nov. 15, M. Painlevé will speak at Cambridge on Nov. 16 on "Résistance d'un liquide au mouvement singulier d'un solide," and on Nov. 17 at the French Institute in London on "Absolu et Relativité." While at Cambridge, M. Pamlevé will receive the honorary degree of doctor of science.

Dr. A. W. Hill, Director of the Royal Botanic Gardens, Kew, sailed for Australia from Toulon on Nov. 4 on the invitation of the Commonwealth Council for Scientific and Industrial Research, Melbourne. Dr Hill expects to reach Fremantle on Nov. 29, and will visit the various botanical, agricultural, and forestry institutions in Western Australia, and will then proceed to Adelaide, Melbourne, Sydney, and Brisbane, to study the various botanical institutions in the different States, under the auspices of the Commonwealth Council. He also hopes to attend the meeting of the Australian Association for the Advancement of Science at Hobart in January next. Dr. Hill will then proceed to New Zealand on the invitation of the Dominion Government, where he hopes to spend some three weeks. He is going on to Java, where he will visit the Botanic Gardens at Buttenzorg on the invitation of the Director, and visits will also be paid to the Botanic Gardens, Singapore, Department of Agriculture, Kuala Lumpur, and the Royal Botanic Gardens, Peradeniya, Ceylon. Dr. Hill expects to return to Kew about April 20 next year. This visit is being undertaken as an outcome of the recent grant to Kew from the Empire Marketing Board, which was made to enable the Director or some senior member of the staff to visit different parts of the Empire to study botanical questions and matters relating to economic botany.

SIR CHARLES MARTIN, director of the Lister Institute, upon whom the honour of knighthood was recently conferred, has been presented with his portrait by the staff of the Institute as a token of personal esteem and appreciation of his great services during the twenty-four years of his directorship. Subscriptions to the portrait were confined to present staff and research workers and to past members of staff during Sir Charles's directorate. The painting of the portrait was entrusted to Mr. Neville Lewis, and the finished work has given much satisfaction The presentation of the portrait took place in the library of the Institute on Oct 28, when Prof. Harden presided over a large company of past and present members of staff and research workers. Prof. Harden referred in eloquent terms to the scientific and administrative ability of the director, his versatility and helpfulness, and above all to his great personal charm and tact which have conduced so greatly to that domestic harmony which has ever been the pride of the Lister Institute.

MEMBERS of the British Association have from time to time discussed the desirability of the Association's applying for a Royal Charter. It has been felt that the Association would be strengthened in its work for the advancement of science by the possession of a charter, but the cost involved has hitherto acted as a deterrent Mr A. A. Campbell Swinton has now generously offered to bear this cost, and the Council has resolved to recommend the General Committee to accept his offer and to authorise the president and general officers of the Association to apply for a charter on its behalf. The possession of a charter would, moreover, enable the Association readily to avail itself of a proposal made by Mr. George Buckston Browne, who, it will be remembered, offered to purchase Darwin's house at Downe for the nation, in response to the appeal made by Sir Arthur Keith in his presidential address at the Leeds meeting of the Association. Mr. Buckston Browne has now expressed his desire that the trusteeship of the estate should be vested in the Association, and the Council will recommend the General Committee to accept this further generous offer

THE preliminary notice of the proposed expedition to the Great Barrier Reef of Australia appeared in NATURE on Mar. 26 last. Circumstances have prevented the departure of the expedition this year, but the preparations have steadily progressed. At the meeting of the British Association at Leeds, a committee of Sections C, D, E, and K was appointed to organise the expedition for 1928. The second meeting of this committee was held at Australia House on Oct. 4, presided over by the chairman, the Right Hon. Sir Matthew Nathan, ex-Governor of Queensland, to whom the inception of the scheme is due. The aims of the expedition, which, it is hoped, will start in April next, are directly scientific, but it is anticipated that their realisation will throw light upon important economic problems. The leader will be Dr. C. M. Yonge, who will be accompanied by a staff including zoologists, botanists, a chemist, a surveyor, and, it is hoped, a geologist.

THE English committee will work in collaboration with the Great Barrier Reof Committee of Australia, the presiding genius of which is H. C. Richards, professor of geology in the University of Queensland, in carrying out the objects of the Expedition, which are "To examine a sector of the Great Barrier Reef from shore to ocean off Cairns, chart it accurately, surveying the associations of plants and animals on its surface, both qualitatively and quantitatively, study the food and power of lime formation in the same, and all such other matters as concern the formation and growth of that part of the reef." The secretaries are Prof. J Stanley Gardiner and Mr. F. A. Potts, of the University of Cambridge. A sum of £8000 is required, of which, with the aid of grants from the Australian Committee, the Royal Society, the British Association, and private subscriptions from members of Section D, a sum of £2250 has already been secured. It is hoped that, in view of the importance of this survey both scientifically and economically, further generous contributions will be made by scientific and commercial bodies, and particularly by private individuals. The treasurer, the Hon. John Huxham, Agent-General for Queensland, or the Secretaries will be glad to hear from persons who may be willing to make 'grants in aid.'

THE Institution of Civil Engineers was founded by half a dozen young engineers in 1818, but it was not incorporated by Royal Charter until 1828, Telford then being president. In view of the approaching centenary of its incorporation, Mr. E. F. C. Trench devoted a part of his presidential address, delivered on Nov. 1, to a historical review of inland transport problems Telford was famous for his roads, bridges, and canals, and in the revolutionary changes in the means of transport effected in the last hundred years, members of the Institution have taken a leading part The earliest roads of England, said Mr. Trench, were due to the Romans and were maintained by the State. Central control, however, vanished in the fifth century, not to return until more than a thousand years later. For centuries upkeep and repairs were unsatisfactory The first Turnpike Act of 1663 led to an improvement, and by the dawn of the railway era, some fifteen hundred stage coaches plied from London. The development of canals took place in the eighteenth century, and these for the first time provided easy and cheap transport for foods and minerals, resulting in a great incentive to industry, but the very success of the canals paved the way for a more flexible and quicker system.

Many railroads were sanctioned early in the nineteenth century, but the steam railway era set in with the Stockton and Darlington Railway of 1825 and the Liverpool and Manchester line of 1830. In the 'forties, hundreds of separate lines were projected, but Parliament was opposed to amalgamation. It is true a select committee of 1844, presided over by Mr. Gladstone, declared that "each new line should be viewed as a member of a great system of communication," yet Parliament in 1853 passed a resolution "that no railway Bill containing any powers of amalgamation, purchase, lease, working arrangement, or other combination of interest between different companies should be read a second time unless all such powers were struck out." The Railway Act of 1921 marked a complete change in the attitude of the Legislature Referring to the present position of the railways, Mi Trench showed what the companies have done to improve the services and yet effect economies. With the coming of the road motor vehicle, the virtual monopoly of the railways has come to an end. Railways, however, have spent £1,200,000,000 on land and tracks and expend £13,000,000 per annum in maintaining the tracks, while road vehicles found their track ready free of charge. Equity requires that the cost of the roads should fall on the road-users. In concluding his address, Mr. Trench said "that great and rapid as has been the advance achieved by the labours of the engineer . . . the true progress of civilisation depends equally upon corresponding developments in the less material fields of human thought and endeavour "

THE International Commission on the finds of alleged high antiquity at Glozel which was appointed by the Institut d'Anthropologie at the recent congress at Amsterdam is now at Vichy for the purpose of pursuing its investigations on the spot. Its arrival was preceded by that of Dr. Peyrony, who, as already announced, is in charge of the site under the Ministry of Education. The members of the Commission are M. Hanmal (Belgium), M. Pittard (Switzerland), S. Bosch-Guimpera (Spain), M Absalon (Czechoslovakia), Miss Garrod (Great Britain), and MM Ferrer, Peyrony, and Favrot (France). As all the members of the Commission are of proved competence in handling archeological evidence, their findings should inspire confidence both as to impartiality and accuracy. It is to be hoped that they will bring to an end a controversy which has at times been conspicuously free from the atmosphere of calm detachment which is supposed to be appropriate to the discussion of scientific problems.

ALTHOUGH the season's excavations have only just begun, the reports which have appeared in the Timesduring October of the work already carried out at Beisan by the Palestine Expedition of the University Museum of Philadelphia gives further promise of fulfilment of the great expectations from this site As exploration is extended in the lower levels of the eight strata identified, which cover a period of thirtythree centuries and date from the time of Amenophis III. to that of the Crusaders, the results become increasingly important to both the historian and the archæologist. Already this season two Canaanite temples, dated at 1500 B.C., have been discovered. They are the earliest yet known and throw an entirely new light upon early Canaanite religion. In one of the temples were two altars: one for cult objects, the other for sacrifice. An outer sacrificial altar exemplifies details of the methods employed in carrying out the ritual It has a channel to carry off the blood, a socket and peg for tethering the victim, and also a

socket for the pole on which the carcase was dressed. Near by were a sacrificial dagger, the shoulder blade of a bull, and a bronze pendant for suspension on the neck of the victim. On the level identified with the time of Rameses II. was found a door jamb, showing the figure of the builder of the temple of Dagon mentioned in Chronicles.

An earthquake was recorded at Kew Observatory on Nov. 4, commencing at 14 hours 3 minutes 14 seconds GMT. The distance of the epicentre is estimated to be 5540 miles. The New York correspondent of the *Times* states that earthquake shocks were felt along the coast of California on the morning of Nov 4, and that five miles of track belonging to the Southern Pacific Railway in Santa Barbara County were thrown out of alinement but no one was injured.

In his presidential address to the North-East Coast Institution of Engineers and Shipbuilders, delivered on Oct. 28, 1927, Mr. Maurice S. Gibb inquires into the probability of the British engineering industry being able to restore its prestige by lowering its costs of production sufficiently to enable it to retail its wares at attractive prices. He comes to the important conclusion that the industry is not so much in need of scientific investigation as of the ability to apply the scientific knowledge obtained. Valuable work is being done by the various research associations, but the real difficulty begins when the results obtained come to be applied to the everyday work of production in the office and shop. Referring to the factors which assist the industry in benefiting from the results of research, the teachers in technical colleges are commended, and the foundry metallurgist and works laboratory staff are valuable connecting links between science and production.

As examples of advances directly attributable to the proper application of scientific knowledge, Mr. Gibb referred to several improvements in materials and methods The production of special steels has made possible the modern aircraft and the higher cutting speeds of machine tools, and now the stainless variety opens up a new field of utility for iron and steel. Boiler plates, bronzes, and cast iron have also been considerably improved in quality. In regard to methods, the measurement of machine parts is now done much more scientifically and accurately; in mass production, the timing of the production of component parts is more exact; temperatures are accurately measured and recorded, the thermo-couple, by which temperatures at various places can be read at one centre, being now a practical instrument in constant use in engine and boiler rooms, in foundries and in other furnaces.

Another important aspect of the case is the economic effect of oil replacing coal as the principal fuel for power production. Coal is Great Britain's greatest material asset and contributes largely to increase our exports, so that it is in the national interest to develop the use of coal rather than oil. The engine builders and purchasers naturally take a narrow commercial view, and the latter demand and the former produce

the engine that will give the best financial return. However, taking a broader view, the cost of our engineering products will be increased as the coal industry diminishes, and it is therefore a matter of importance to the whole engineering industry. It is not suggested that the development of the internal combustion engine should cease, but rather that the problem should be approached from the opposite direction by further developing the steam engine. Whatever it may have already done, the coal industry itself is invited to assist in the work of investigating the possibilities of the coal-using engine, and this work, being of vital national importance, should receive attention before it is too late.

In his inaugural address to the Institute of Transport, delivered on Oct. 10, Mr. Roger T. Smith discussed the results already obtained on the Swiss Federal Railways (the C.F.F., Chemins de Fer Federaux). One of the reasons of the success of the electrification scheme of the C.F.F. is that an electric locomotive can provide about four times the increase in pull for the same drop in speed which the steam locomotive can give. This summer the average trailing load hauled on the C.F.F. by an electric locomotive was 100 tons greater than the average load hauled by a steam locomotive. At the same time, the average speed was increased by about 20 per cent. Unlike the steam locomotive, the electric locomotive can go up steep gradients with very little loss of speed. The saving of time over steam working in ordinary stopping passenger trams is considerably greater than for express trains owing to the high accelerating power of the electric locomotive. Owing to the special conditions in Switzerland, for example, the steep gradients and the many lengthy tunnels, electric traction has many advantages. Many international trains also run over the Swiss lines. It is difficult, therefore, to deduce from these results what the corresponding results in Britain would be. Mr. Roger Smith, however, has made careful estimates for main-line electrification schemes in Great Britain over long routes. He finds that the savings in working expenditure, as compared with steam, will pay on the cost of electrification from 5 per cent on fairly busy lines to as much as 12 per cent. in lines fully worked with dense mineral and goods traffic throughout the twenty-four hours.

ELECTRICITY was first introduced into mines as an obvious solution of the problem of driving in a confined space machinery for coal cutting, for haulage, and for working pumps. Safety of life is the dominant factor, and every modern development of underground gear is in this direction. In an article in the Electrical Times of Nov. 3, Prof. W. M. Thornton lays stress on the improved lighting of the underground roads and on the elimination of the horse as a means of traction. The oil lamp is useful as a gas detector in mines, but it will inevitably give place to portable electric lighting sets. Research has shown how much the comfort of the worker depends on the absence of a feeling of apprehension. There is reason for believing that this nervous feeling combined with bad lighting produces

that singular eye disease called nystagmus, the ineidence of which seems almost to be sporadic. The great electrical haulages found in many pits are the most active of all the means by which electricity saves the miner. The whole safety of underground workers, as in that of pedestrians in a busy town, depends on the probability of a set of dangerous factors occurring simultaneously. It is to reduce this probability that the Safety in Mines Research Board investigations are directed The spark occurring when an electric lighting circuit is broken may cause an explosion Prof. Thornton has shown that it is possible to go on breaking a 500-frequency 200-volt lighting circuit carrying 20 amperes in an inflammable mixture of coal gas and air for hours without anything happening. With 200 volts direct current, ignition followed at once when the current was 1 ampere. This suggests the possibility of using higher frequencies for lighting in mines. It has to be remembered, however, that by far the greatest number of accidents in mines is caused by falls of the roof and side. The only remedy is to erect with greater care and use improved mechanical means of support

At the ordinary scientific meeting of the Chemical Society on Thursday, Nov. 8, Sir Joseph J. Thomson was elected an honorary fellow of the Society.

WE much regret to announce the deaths of Dr. D. G. Hogarth, C.M G, Keeper of the Ashmolean Museum, Oxford, and president of the Royal Geographical Society, on Nov. 6, aged sixty-five years; and of Sir William Galloway, the distinguished mining engineer, on Nov. 2, aged eighty-seven years.

The annual general meeting of the Mineralogical Society was held on Nov. 1, and the following officers were elected —President, Dr. G. T. Phor., Vice-Presidents, Sir. John Flett, Sir. Thomas. Holland; Treasurer, Mr. F. N. Asheroft; General Secretary, Mr. W. Campbell Smith (Natural History Museum, S. Kensington, S.W.7); Foreign Secretary, Dr. J. W. Evans; Editor, Dr. L. J. Spencer.

THE British Mosquito Control Institute, Hayling Island, Hants, announces that arrangements have been made for short two- or three-day courses of instruction in mosquito control work to be given during the first week of each month. The first course will commence on Tuesday, Dec. 6, and will include (1) lectures dealing with the life-history, habits, and structure of mosquitoes, and various methods of control; (2) practical field work in the application of remedies; and (3) identification of mosquitoes in the laboratory. The instruction provided is intended primarily for those who wish to obtain an elementary knowledge of the subject in the shortest possible time. The two-day course is sufficient for this purpose, but those who wish to pursue their studies further will have an opportunity to do so on the third day. The Institute is also available for the use of research students, and is fully and admirably equipped for all these purposes. The courses will be of interest not only to persons going abroad, but also—and perhaps especially—to medical officers of health and others in Great Britain seeking information regarding the control of local mosquito pests. Full information can be obtained from the Director of the Institute.

A SPECIAL number of the Zeitschrift fur physikalische Chemie has been dedicated to Prof. Ernst Cohen, of the University of Utrecht, to commemorate the twenty-fifth year of his professorship.

Readers interested in South Africa should obtain catalogue No. 501 of Messrs. F. Edwards, Ltd., 83 High Street, Marylebone, W 1, which gives the titles, and, in many cases, other particulars of some 700 books, etc., relating to that part of the globe. A later catalogue, No 502, deals with nearly 900 works relating to the Near East and Egypt.

Prof. A. N Whitehead has a new book entitled "Symbolism: its Meaning and Effect," appearing through the Cambridge University Press. The same house will publish almost immediately "Psychology and the Soldier," by F. C. Bartlett. The work aims at showing how a knowledge of psychology and social psychology can be brought to bear upon the selection and training of recruits, the maintenance of discipline, and the development of morale. It also gives a brief account of some of the mental disorders of warfare and of their treatment.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned .—A special librarian at the Institute of Metals-G. Shaw Scott, Secretary, 13-14 Members Mansions, Victoria Street, S.W.1 (Nov. 15). A temporary draughtsman under the Directorate of Technical Development, Air Ministry —The Secretary, Air Ministry, Adastral House, Kingsway, W.C 2 (Nov. 18). A head of the department of mechanical and civil engineering at Loughborough College — The Principal, Loughborough College, Leicestershire (Nov. 21) A junior research officer in the Institute of Animal Pathology, Royal Veterinary College—The Director, Institute of Animal Pathology, Royal Vetermary College, Camden Town, NW.1 (Nov. 29) An assistant in the pathology department of the University of Aberdeen-The Secretary, The University, Aberdeen (Nov. 30). Two research assistants in the School of Tropical Medicine Laboratory, Freetown, Sierra Leone—The Hon. Dean, School of Tropical Medicine, Pembroke Place, Liverpool (Dec. 1) A telephone engineer under the Egyptian State Railways—Office of the Chief Inspecting Engineer, Egyptian Government, 41 Tothill Street, S.W.1. A teacher of advanced engineering calculations at the Central Polytechnic, Croydon-The Principal An assistant at the Harper Adams Agricultural College, for special crop experiments— The Principal, Harper Adams Agricultural College, Newport, Salop

# Our Astronomical Column.

Shower of Large Meteors.—Mr. W. F. Denning writes that "on Oct. 31 an assistant watching the sky from his garden counted 51 meteors during the right. Of these, live were as bright as, or brighter than, Venus, and several others were equal to Jupiter The objects were not directed from one system but from several, the principal of which were as under:

 $\epsilon$  Arielids:  $42^{\circ} + 23^{\circ}$ .  $\alpha$  Arielids: 33 + 19. . . . 12 meteors. 8 meteors. 8 meteors. The bright meteors were nearly all conformable to one or other of these streams. The two in Aries have often been observed before, but the Andromedids have been very little in evidence at the end of October in past years. One of them, as bright as Venus, observed at 20h 32m GM.T. on Oct. 31, was also seen by Mr. Pye-Smith at Beckenham, Kent, as it passed through the central region of Perseus and disappeared a little to the left. The radiant point is indicated at  $27^{\circ} + 43^{\circ}$  and the height of the meteor 65 to 27 miles above the mouth of the Thames from north of Margate to east of Southwold The observer at Kent mentions that the light of the object illuminated his garden, and no doubt many metropolitan residents witnessed the flight of the meteor"

The Nebulosity around Nova Aquile III.—Shortly after the appearance of Nova Aquile III. (1918), Prof. Barnard discovered a bright nebulous envelope, about 0"7 m diameter, surrounding the star. Later observations by Barnard and Aitken showed that this envelope was gradually expanding and fading, until in 1921 it became too faint for visual observations. A series of photographs were taken in 1926 with the Mount Wilson 100-inch telescope, and the results are described by Hubble and Duncan in the Astrophysical Journal, vol. 66, p. 59. The photographs show the envelope as a

sharp circular disc, of about 16" diameter, with the star in a central position. The expansion therefore appears to have continued at a uniform rate of 1" 0 annually, which is in accordance with the early visual observations. Assuming a linear rate of expansion of 1700 km./sec. (based on radial velocity observations from early spectrograms), this would imply a parallax of 0" 0028, corresponding to a distance of 360 parsecs.

IDEAL LUNAR LANDSCAPES.—L'Astronomie for September contains an interesting article by M. Lucien Rudaux, contrasting lunar and terrestrial landscapes. The blackness of the sky and the absence of all aerial perspective, in addition to the great difference in the character of the surface features, increase the difficulty in making correct mental conceptions of the appearances that would be presented to an observer on the moon. The author gives a series of carefully designed pictures of various lunar landscapes. In one of these we are supposed to be standing at the bottom of a deep crevasse. One wall is brightly lit up by the sun; the other is faintly visible by reflection from it. The shadows must be far from black in regions where a large extent of sunlit cliff is in the field of vision Another picture shows the aspect of one of the smaller craters soon after sunrise; in another we are situated in the centre of the floor of Plato; only a few of the highest summits in the surrounding rampart are visible, the rest of it is below the horizon. There is also a picture supposed to be taken at the moment before sunrise. A portion of the corona and chromosphere have already risen, also the zodiacal light. A reconstruction is given of the isolated mountain Pico near Plato. It is much less precipitous than one is apt to imagine from its tapering shadow. In fact, its height appears to be only one-tenth of the diameter of its base. A series of careful drawings of this kind are a useful aid in forming correct notions of the nature of the lunar surface.

THE DISTRIBUTION OF MAN-In Scientia for October, Prof. Mendes-Corrêa discusses the factors which must be taken into account in studying the question of the dispersion of early man over the earth. It must be remembered that early man, although man is the most widely distributed of the primates to-day, did not possess the mobility of modern man or his cosmopolitan character. His nomadism was restricted. The sea was a formidable obstacle, as it still is to-day to many coastal or insular peoples. In the earliest times geographical conditions canalised 'migrations and man was the slave of his environment, though gradually he came to react on it. Present ethnical distribution is no sure guide, and the continuity of occupation in any given area must be traced equally with the changes in an environment which may have modified its suitability for occupation. Further, in framing generalisations for large areas, local variations must not be overlooked, as for example in the clearings of equatorial Yet even so, forests and the oases of desert areas. geographical factors are not alone to be taken into account. Safety, the surroundings, adaptability for exploitation, social and political organisation, and the like must be considered. Turning to the place of origin of man, palæolithic man lived in Asia, as a number of discoveries show, the Siwalik Hills have produced fossil remains of early apes, a Neanderthal skull has been found in Palestine, and the peoples of to-day include a number of very primitive types. On the other hand, Africa has a palæolithic industry, remains of primitive types of early apes and man and the chimpanzee and Yet again all around the Indian Ocean and its archipelagoes are found localised groups of inferior types which require consideration. The negritoes of Malaya and the Australians may be early immigrants, and in addition there are Puhecanthropus from Java and Wadjak man. Discoveries in the Fayum, in the Siwalik Hills, and South Africa might point to a peripheral distribution of both anthropoids and Catarrhine apes of which the lemuroids of Madagascar might form part. The area of the Indian Ocean might thus appear to have been a centre of dispersion.

FIJIAN ROUND BARROWS.—In Man for October, Mr. A. M. Hocart corrects an inaccuracy in Williams's account of Fiji which has been brought to light by the use of a woodcut from that author's work as evidence of the existence of round barrows in Fiji. As a result of inquiry, Mr. Hocart has ascertained that Nautuutu. the barrow in question, was undoubtedly square. He has, however, now discovered among his own notes a record of a round barrow at Namoka on Vanua Levu which he had overlooked. He also observed a square mound at Nambuna and an oblong mound in Scanganga, so that three forms were found together. According to the native account, the temple was round, with one door and with pointed apex. It was built of the same materials as a house but ornamented. It was not built on the top of the mound, but the mound was inside it. This mound was the holy land on which no one might tread. In Ceylon there was, and still is, a custom of building a temple not on, but over the smaller topes. The author has already traced the tee of a Buddhist tope to a square shrine built on the tumulus. It is suggested that the house on the tumulus has petrified in a process of conventionalisation and its meaning been forgotten, and that another house has been erected on the whole. In Fiji this process has not taken place, and the house over the mound is not a reduplication but an alternative, which may have existed before the separation of the Indian and Fijian round barrows.

NORTHERN TINTINNIDS — Dr. E. Jorgonsen of Bergen gives an excellent account of the Tintimudæ in the North Sea and Baltic ("Die Tierwelt der Nord-und Ostsee," Lieferung 8, Teil II. c: Tintimidæ. Leipzig: Akademische Verlagsgesellschaft, 1927.) This group is little known except to plankton workers, and these know it better than any of the other Infusoria, as it contains the commonest and most easily recognisable plankton forms, both neutic and oceanic. A tintimid lives in a beautifully formed vase-shaped case or house, which remains intact after the death of the animal forming and inhabiting it. These cases are used as the basis of classification of the various genera, fitteen being recorded from this area; Tintinnopsis, the best-known genus, having ten species, the case being covered with extraneous particles such as sand grains and coccoliths. genera may have a perfectly smooth and hyaline case and some may be ringed spirally at the open end showing growth lines, others having regularly pierced cases like basket-work. The method of formation and structure of these cases is extremely complicated and difficult to elucidate. Inside the case the infusorian is fixed by a thread-like portion of the body, either at the bottom or the side: only very exceptionally is it loose. When actively swimming, the broad end, aimed with ciliated plates, projects from the case and, presumably, as it swims sweeps into the body small living creatures on which it feeds—flagellates, dinoflagellates, and diatoms. No worker knows the group better than Dr. Jorgensen, and the present survey is exceptionally welcome and useful to planktologists, as the Tintinnide in "Nordisches Plankton," the sister publication of "Die Tierwelt," has not yet appeared.

SEX-LIMITED HORNS IN CATTLE -From the experience of cattle breeders it has long been known that in the domestic breeds the polled or hornless condition usually behaves as a simple dominant to the horned condition. Exceptional cases are now being recorded, however, in which horns are a sex-limited character in crosses, being generally present in males and absent m females. Such cases are recorded by Mr. A. D. Buchanan Smith (Jour. of Genetics, vol. 18, No. 3) in crosses between native-horned cows in Rhodesia and Aberdeen-Angus polled bulls. The heifers produced were all polled, and the bulls nearly all had horns. Among the wild white park cattle of Britain there are horned and hornless herds, the Chillingham and Cadzow herds being horned, while several other herds are polled. Matings of horned with polled in these herds give an abnormally small number of polled calves, so that here also factors are present which modify the ordinary recessiveness of horns. Other records of a similar kind are cited, and the statement of Prof. Cossar Ewart is quoted, that several species of cattle with horned males and hornless females occur in the lower Phocene. This older condition appears to have persisted in some strains down to the present time. That such sex-limited inheritance may occur in a modern herd is indicated by a short record (Mr. O. O. Churchill, in Jour. of Heredity, vol. 18, No. 6) of a registered herd of Hereford cattle in North Dakota, in which matings between horned bulls and polled cows produced polled heifers and bull calves with horns or scurs. Future studies will throw light on the nature of the difference between

simple recessiveness and sex-linked inheritance of horns. That cattle were originally hornless is clear from the Phocene records of Leptobos species without horns. Mr. R. C. M. Auld (Jour. of Heredity, vol. 18, No. 7) gives a number of illustrations and records showing that the polled condition has persisted through historical time. Polled cattle existed in Egypt, 2150 B.C., they are shown on coins from Mytilene in the fifth century B.C and in prehistoric Pictish carvings in Scotland Palæolithic drawings of polled cattle, probably domesticated, are found in a French cave of the Madeleine period. The original hornless type thus gave rise to a horned race in which the horns were at first confined to the males. Horns are not considered an advantage in fighting between males, but their possession is useful in driving off carnivorous enemies. Whether they arose as a single mutation or in some other way, their origin would appear to have been a relatively sudden development.

TERTIARY MOLLUSCA OF JAPAN.—Reference has previously been made in these pages (NATURE, Sept. 11, 1926, p. 389, and Dec. 4, 1926, p. 819) to the important papers by Prof. Matajiro Yokoyama on the Tertiary Mollusca of Japan A further series of six papers by the same author has just arrived (Jour. Fac. Sri. Imm. Ilmw. Tokyo. sect. II., vol. 1). The Fac. Sci. Imp. Univ. Tokyo, sect. II., vol 1). The collections now dealt with come from the province of Tosa, in the Island of Shikoku or Nanka, and on the main ısland from the Atsumı peninsula and southern Tôtômı, the neighbourhood of Tokyo, and western Shimôsa and southern Musashi, as well as the oilfields of Akita in the province of Ugo. The same method is adopted as before in each paper: a brief but clear introduction discussing the topography and geology of the area in question, with a list of the geology of the area in question, with a list of the fossils, is followed by descriptions of the species and illustrative plates. In two cases useful indexes are appended. Taken together, these papers total 145 pages with 15 plates. With regard to the fauna of the Musashino beds (Pliocene) the author points out that it is more northern than that of the recent adjacent seas. A few of the species present are also found in the English Crags. There is inevitably a large number of new species.

THE ADELAIDE DISTRICT, SOUTH AUSTRALIA.-A paper read at the Royal Society of South Australia on Sept. 8, by Dr. C. Fenner, described the geographical development of the Adelaide district, South Australia. It was, in the Middle Kainozoic, a wide well-timbered plain of ancient rocks, with meandering streams, broad swamps, and a warm temperate climate. This plain sank below sea-level, and the submergence lasted throughout the Miocene and part of the Pliocene, after which it was slowly uplifted as a low-level limestone plain. About the beginning of the Pleistocene were formed two great semi-circular sunklands bounded to the east by the Mount Lofty and Flinders Ranges The lowest parts of the sunklands were occupied by Lake Torrens and the Spencer-Vincent Gulfs. The Mount Lofty Highlands were covered with Miocene limestone; but this cover has been mainly stripped off by river action, which also carved out deep valleys and covered the lowlands with alluvial material. The gorge of the Torrens River is attributed to the Pleistocene, and the upper valleys to possibly the late Phocene. The country was colonised about a century ago, but its development was hampered by the mountain barrier between the Adelaide plains and the Murray Valley. The rate of growth of progress of the population has recently been greatly accelerated, and if the present rate continues until 1940 the population would amount to 450,000. By 90 years growth it has reached

320,000. Adelaide is now the chief market and port of the State of South Australia, and is a rich garden owing to the conjunction of favourable climatic conditions, city site, and general amenities.

Mountains of North-Eastern Siberia.—During last year a series of important geographical discoveries were made by S. V. Obruchev during the course of his exploration of the little-known region traversed by the Indigirka and Kolyma Rivers. A very considerable mountain system was found trending across the upper Indigirka, reaching heights of 3000-3300 metres in places A preliminary report appears in the Zeitschrift fur Gletscherkunde of July, 1927. Although no glaciers were seen, the mountains were found to be capped with perpetual snow, and the landscapes and surface deposits clearly indicated very extensive glaciation in the past. Mountain ranges to the east and west have already been mapped, and altogether a system 1000 km. in length and roughly 300 km. across is now known, forming an arc concentric with the previously known outer arc of Verkhoyansk-Anadyrsk. From the point of view of Asiatic tectonics and the former glaciation of Siberia, Obruchev's work is of fundamental value, and further details will be eagerly awaited.

THE GEOLOGY OF THE SPRINGBOK FLATS.—A memoir of more than usual interest on the northeastern part of the Springbok Flats has just been published by the Geological Survey of South Africa (Explanation of Sheet 17, 1927, by Dr. Percy A. Wagner). Points of particular importance are the descriptions of the Rooiberg beds (Transvaal system) and their associated keratophyres and nodular felsites; the marble formations of the Dolomite series; the igneous rocks of the Bushveld complex; the local development of the Karoo system and the Stormberg volcanics; and the general physiography of the 'Flats'. Interesting evidence of climatic changes is presented. There is clear proof of an epoch of (a) vigorous erosion succeeded by (b) an and period which led to the aggradation of the valleys with silt; and finally (c) renewed vigorous erosion in which the present streams have cut down to the coarse gravel or bedrock with which the valleys are floored. The rejuvenation is not due to a steepening of grade, but to an increase of rainfall; and Roger's contention that there is no ground for the common opinion that South Africa is drying up thus receives strong support.

MAGNETIC OBSERVATIONS IN THE NORTH.—The Danish Meteorological Institute has initiated a new series of occasional publications (in octavo form) entitled Communications Magnétiques. The first two issues, lately published, contain five interesting papers, of which the most noteworthy is perhaps that written by the Director, Dr. La Cour, "on the mean error of the monthly means of the magnetic elements observed at the observatory of Rude Shov." This able and valuable paper consists of a comparison of the apparent changes in the monthly means obtained at eleven European observatories during 1911-1920, and throws light on the probable freedom (or otherwise) from small systematic errors in the absolute magnetic observations at these stations. Another paper describes the novel and apparently satisfactory method of direct determination of scale values for the magnetographs of the recently instituted Danish observatory at Godhavn. Greenland; the daily variations of the elements are so great that the scale values can be measured by taking absolute observations at different times of the day. The other three papers deal with the heating of the upper atmosphere by eathodic rays (connected with auroræ) from the sun; and with the values of the magnetic elements at Rude Skov during the recent eclipse, and during a still more recent magnetic storm -of July 22, 1927.

Tidal Research.—The eighth annual report of the Tidal Institute of the University of Liverpool indicates a steady growth in the work of tidal analysis and prediction executed by the Institute for the Admiralty and various port and harbour boards in Great Britain, and for the Hydrographic Offices of Canada and China—The methods of computation have been further improved and simplified. Various improvements have also been made in the tide-predicting machine of the Institute; one of these, the fitting of ball-bearings for the pulleys, has reduced the friction and practically eliminated the small elastic variations in the length of the tape which had been found due to friction at the pulleybearings. The director, Prof. Proudman, and the secretary, Dr. Doodson, have continued their studies on the dynamical theory of tides.

X-RAY TUBE RADIATION.—In the issue of the Physikalische Zeitschrift for Sept. 15, Drs. D. Nasledow and P. Scharawsky, of the Rontgen Institute, Kiev, sum up their conclusions as to the variation of the intensities of the characteristic lines and of the whole radiation from X-ray tubes with the current through the tube. The intensity of radiation is measured by the current transmitted through a tube containing air ionised by the radiation under the action of a constant electromotive force sufficient to produce the saturation current. Anticathodes of copper, molybdenum, palladium, silver, and tungsten have been investigated, and all give for currents of a few milliamperes through the tube, intensities of radiation proportional to the current, up to a critical value which increases with the atomic weight of the metal from 4 to 8 milliamperes, after which the increase of the intensity is proportional to the increase of the current. The change of slope of the intensity-current graph at the critical point increases as the electromotive force on the tube increases.

THE ELECTRONIC STRUCTURE OF ATOMS AND THE Periodic Classification.—The relation between atomic structure and the periodic classification is discussed in a preliminary paper by J. D. Smith Main in the Journal of the Chemical Society for September. A classification is put forward which facilitates the interpretation of atomic structures without suppressing the chemical importance of the usual eight valency groups. Instead of expanding the groups in the periodic table, as has usually been done when the mathematical interpretation of atomic structure has been the chief interest, the author considers that the chemical properties are best brought out by its abridg-This involves the relegation of a considerable number of elements in the long periods to the position of 'transitional elements.' Elements in the abridged periods are regarded as having valencies which vary only in multiples of two, difficult exceptions being otherwise explained. Eight groups are thus found, divided into an 'alkaline' group, an 'amphoteric' group, and a 'non-basic' group, the valencies running in units from I to 7 and then falling to zero, or else, in each group, differing by 2, 4, or 6. Two extra tables of transitional elements are then received. of transitional elements are then required, one contaming the rare earth elements. The complete table is then formed by combining these sets of elements. This complete table differs only slightly from the usual table in appearance, but the so-called 'transitional' elements are now distributed in the body of the table

as well as occurring in Group VIII. The rare earth elements must form a 'footnote' to the table

CO-ORDINATION COMPOUNDS OF QUINQUEVALENT MOLYBDENUM.—The September issue of the Journal of the Chemical Society contains an account of a study of salts of the types R<sub>2</sub>[MoOCl<sub>5</sub>], R|MoOCl<sub>4</sub>, H<sub>2</sub>O] and [MoO<sub>2</sub>X<sub>2</sub>, 2H<sub>2</sub>O]R. One of the most interesting features of certain of these salts is the large number of ions produced when they are dissolved in water, the various stages of ionisation being accompanied by distinct colour changes. At infinite dilution, the complex salts R<sub>2</sub>[MoOCl<sub>5</sub>] yield ten ions and consequently have very high molecular conductivities. Several new salts have been prepared.

GRAIN GROWTH IN COMPRESSED TUNGSTEN POWDER. -The only systematic examination hitherto on this subject is that due to Sauerwald, who considered that grain growth occurred at the same temperature of 2500°-2700° C. irrespective of the method of preparation of the powder or the pressure. Smithells, Pitkin, and Avery, in a paper presented at the September meeting at Derby of the Institute of Metals, have re-examined the subject. From determinations of the electrical energy required to heat the powder, the density and the microscopic condition of the product, they have shown that the temperature of sintering is a function both of grain size and of the pressure used in forming the bar. Using powders the mean particle size of which varied from  $0.6\,\mu$  to  $35\mu$  and pressures from 8 to 32 tons per sq. m, the temperature at which grain growth could first be detected varied from 1100° to 1500° K. The finer the powder and the greater the pressure the lower was the temperature necessary for growth. It is known that if the hydrogen atmosphere in which the tungsten is heated contains even a trace of moisture, the structures obtained are greatly affected. In this work the greatest care was used in drying the gas, but the oxide originally present in the powder may have influenced the changes observed.

THE SOLUBILITY OF CEMENTITE IN a-IRON - The extent to which carbon is soluble in a-iron, though admittedly it cannot be large, has not yet been satisfactorily settled. A paper by J. H. Whiteley to the recent Glasgow meeting of the Iron and Steel Institute carries the matter somewhat further and shows that there is a marked merease in this solubility as the temperature is raised, and at 720° C. the solubility is about 0 03 per cent. At 630° C. it is still appreciable and the carbide may be retained in solution in the iron by rapid cooling. The quenched material on tempering precipitates carbide at or below 250° C., and as the temperature of tempering is raised the minute globules thus formed travel to the crystal boundaries. The velocity of this migration increases with temperature, and at 550° C. is very great. By quenching below the Acl point, sufficient carbide is retained in solution by the iron as compared with that in a slowly cooled sample appreciably to increase the Brinell hardness. During slow cooling the carbide is thrown out of solution on the existing particles and the inference is drawn that slowly cooled ferrite in ordinary steels contains little if any carbon in solid solution. This is in accord with the conclusions of Yamada and Yensen, who place the solubility limit at less than 0 01 per cent. As the purity of the iron is reduced by the presence of other elements in solid solution, the solubility of carbide in the a-ferrite is in all probability correspondingly reduced and the temperature at which the solubility commences to increase rapidly is somewhat raised.

# Draft Statutes for the University of London.

WE published on July 10, 1926, a leading article on the reconstitution of the University of London The position at that time was that the Government had redeemed its pledge to introduce legislation "to make further provision for the University of London" by introducing a Bill in the House of Lords, and this Bill had been accorded its second reading on the motion of the Earl of Balfour Nov. 19, the Bill received its second reading in the House of Commons on the motion of Lord Eustace Percy, president of the Board of Education, in a conciliatory and closely-reasoned speech. Dr. Graham Little, the member for the University, led the opposition in a vigorous speech, urging that any necessary changes in the constitution of the University should be made by those having internal knowledge of its work and aspirations. "It is in the interests of freedom," he said in his peroration, "the freedom of the University and the freedom of the students, especially of external students, that I beg the House to reject the Bill." Capt. Fairfax, who seconded the rejection, was supported by Sir Richard Barnett; but most of the speakers, including Mr. Trevelyan, Mr Withers, Sir Alfred Hopkinson, Mr Lees Smith, Mr Hilton Young, accepted the main principles of the Bill, which passed its second reading without a division. The proceedings in Standing Committee on Dec. 2 produced two important Government amendments, the first safeguarding the interests of theo-logical colleges whose position is differentiated from that of other colleges in their not receiving financial support from the Government; and the second, in the form of new clause—a concession implementing the Government's declaration that there was no desire or intention to establish State control of the Universityauthorising recommendations to His Majesty Council from persons or bodies representative of the University regarding the appointment of the crown members of the council of the University. received the Royal Assent on Dec. 15, and its short title is "University of London Act, 1926."

The chief purpose of the Act, in accord with precedents recently adopted for Oxford and Cambridge, and followed also for London in the earlier re-constitution under the Act of 1898, is to appoint commissioners to draft new statutes for the University. Mr. Justice Tomlin is chairman, and the other commissioners are Sir Amherst Selby-Bigge, Sir Cyril Cobb, Sir Josiah Stamp, Sir Cooper Perry, Dr. A. D. Lindsay, Miss Bertha Phillpotts, and Prof T. P. Nunn. Sir Henry Sharp has been appointed secretary. The duty of the commissioners is to make statutes for the University "in general accordance with the recommendations" of the Departmental Committee of the Board of Education, appointed by Mr. Trevelyan in 1924 "subject to any modifications which may appear to them to be expedient." The first draft of the proposed statutes has been published by the commissioners, who invite representations thereon pursuant of sub-section (2) of section 4 of the Act.

suant of sub-section (2) of section 4 of the Act.

Under section 21 of the draft statutes, a "Council of the University" is to be appointed of 16 members with power "to determine finally any question of finance arising out of the administration of the University or the execution of its policy, or in the execution of any trust requiring execution by the University." Its members are the chancellor, vice-chancellor, and chairman of convocation ex officio, six members of the senate appointed by the senate, four by His Majesty in Council, two by the London County Council, and one co-opted member.

Under clause 39, the senate is to consist of 50 (or possibly 51) members, namely, the chancellor, the vice-chancellor, the chairman of convocation, and the principal ex officio, 16 by convocation to be elected by the graduates according to faculties, 16 by the faculties composed of teachers of the University, 11 by colleges and medical schools, and 4 co-opted members. The colleges which are to be granted direct representation are: University, King's, Bedford, Birkbeck, East London, Imperial, London School of Economics, Royal Holloway, and Westfield (the last two have been added to the list published in the report of the Departmental Committee), and two representatives of the general medical schools to be elected by a meeting of the deans of such schools. The senate is to be "the supreme governing and executive body of the University in all academic matters." The vice-chancellor need not an electron be a member of the senate, and if he is not, the total membership of the senate will be increased to 51.

There are to be five standing committees of the senate, namely, the academic board, the board for external students, the collegiate board, the university extension and tutorial classes board, the matricula-The academic tion and schools examination board. board is to include, in addition to the 16 faculty members of the senate, 9 other persons appointed by the senate. The principal is to be chairman of the collegiate board, to be composed of college principals and to be responsible largely for the co-ordination of the teaching work of the University. No important change has been introduced into the organisation of faculties and boards of studies, but the regulations governing the admission of schools to the University are to be made more stringent. New schools, other than theological colleges, will be prohibited from applying for or receiving any money from any public body otherwise than through the council of the University, and will not be allowed, except with the consent of the council, to appeal publicly for money or accept any benefaction to which any onerous condition is attached

Under the existing statutes based on the Act of 1898 the senate is "the supreme governing and executive body of the University." Apart from the powers to be assigned under the new statutes to the council, the senate under the new statutes (Draft Statute 48) "may delegate or authorise the delegation of any of their powers to any standing committee of the senate or to any subordinate committee or body."

The appointed area for the admission of new schools is the administrative County of London, including the County of the City of London. But teachers of the University may be recognised in institutions situated in this area or in Middlesex, Surrey, Kent, Sussex, Essex, or Hertfordshire. Also the senate may admit as a school of the University any public educational institution situate outside the County of London which is wholly or mainly devoted to the pursuit of some branch of University study, which cannot, in the opinion of the senate, be adequately pursued in any institution within the London area or for which no recognised teacher or adequate body of recognised teachers is available in the larger area for such recognition (Draft Statute 106).

Under clause 134, a new power is to be given to the senate to "revoke any degree, diploma, certificate, or distinction conferred by the University, and all privileges connected therewith, if the holder shall have been convicted in a court of law of felony or of

any misdemeanour which, in the opinion of the senate, by reason of its immoral, scandalous, or disgraceful nature, renders him unfit to hold any such degree, diploma, certificate, or distinction"; and on good cause shown to restore the same degree, diploma, certificate, or distinction, without further examination.

Special college examinations, both at the intermediate and final stages, are authorised by draft statute 137.

A list of schools of the University "immediately prior to the appointed day" is printed as a schedule. The office of the commissioners is 5 Clement's Inn, W.C.2.

# The Gibraltar Skull.

A Ta meeting of the Royal Anthropological Institute held on Tuesday, Nov. I, Mr. H. J. E. Peake, president, in the chair, Miss Dorothy Garrod described the excavations at the Devil's Tower, Gibialtar, in which she had discovered the skull now known to be a relic of Neanderthial man. Mr. L. H. Dudley Buxton gave a description of the skull, and Prof. G. Elliot Smith described the endocramal cast, from which it has been possible to observe the main features of the conformation of the biam.

Miss Garrod gave an account of the excavations in the spring of 1926 in the cave, which was first observed by the Abbé Breuil during the War when excavation was impossible. The portion of the skull first discovered was found embedded in hard travertine, from which it was blasted with dynamite The fragments were near one another but not contiguous. In the autumn, excavations were resumed, and the cave and talus were cleared down to bed rock, where further fragments of the skull, including part of the lower mandible, were discovered The associated remains of fauna indicated that the skull was of Pleistocene age. The differences in the species represented here and those from other sites of the same period are attri-They are characteristic buted to the warmer climate of the Spanish Pleistocene age. All the implements discovered in the different strata were of Upper Mousterian type. The cave had apparently been used as a place of habitation, but probably only at cortain seasons of the year.

Mr. Buxton said the human remains discovered by Miss Garrod in her excavations include the following bones of a human skull: the frontal, the left parietal, the right half of the maxilla, the right temporal, the greater part of the lower mandible, and four milk teeth, two molars being still in their places in the upper and lower jaws respectively, unfortunately not on the same side.

Although there are certain gaps which make reconstruction a matter of considerable difficulty, there is no reasonable doubt that the bones belong to the same individual, as many of the pieces fit together, and those which do not, that is, the temporal and the parietal, can be shown to belong to the same skull by duplicating the bones, so that a left temporal is made to fill up the gap on one side and a right parietal the gap on the other.

Apart from other details, the age is best indicated by the teeth. The first permanent molars were never erupted, but were nearly ready to erupt. It is therefore reasonable to put the age at between the fifth and sixth years, as the permanent molars erupt in the latter year. This is merely an indication, as we have no evidence that the teeth of Neanderthal man erupted exactly at the same time as those of modern man. It seems probable from the size and general characters that the sex was male, and that the La Quina child was therefore female.

Although, no doubt owing to the age of the specimen, the brow ridges have not yet attained that development which is so marked a feature in Neanderthal man, the remains certainly belong to a member of that branch of the human family. Apart from details the most striking characters are the low flattened

form of the vault and the form of the massive jaw. The teeth when viewed by X-rays show the 'taurodont' appearance, both in the decidious and uncrupted permanent teeth, which is not the least of the characteristic features of Neanderthal man.

Prof. Elliot Smith said Miss Garrod has made it clear that the fossilised skull fragments found by her can be referred with certainty to the Upper Mousterian phase of culture, and Mr Dudley Buxton has shown that they formed a part of a five-year-old child who conformed to the Neanderthal type. Hence it is a matter of some interest to discover in the endocranial cast features that sharply differentiate it from those of all other known representatives of the Neanderthal species. There is a fullness of the prefrontal and parietal areas such as is unknown except in *Homo sapiens*. Yet the general form of the cast conforms to the Neanderthal type.

The question naturally arises whether this apparently exceptional development of the brain may not be due to some pathological condition, such as hydrocephalus, causing a general expansion of the cerebral hemispheres. While the possibility of hydrocephalus cannot be wholly excluded, there are reasons for regarding such an explanation of the condition as improbable. The excavations upon the inner table of the cranium that correspond to the convolutions are exceptionally distinct for a young child's skull, and the ridges that separate them are too salient to be reconciled with an hypothesis of hydrocephalus.

Hence it appears that the unexpected form can be accepted as definite evidence of an altogether exceptional development of the prefrontal and parietal areas for a member of the Neanderthal species. In Neanderthal man the most obtrusive feature of the endocranial east, as Anthony and Boule have emphasised, is the small size of the prefrontal area. But the series of Neanderthal crania that are now available for study reveal a considerable range of variation in the size of the frontal territory. Admitting that the Devil's Tower skull differs from the rest in an exceptional expansion of those areas of the brain which confer upon Homo saprens his most distinctive attribute, it must not be assumed that the Gibraltar child represents a link between the two species. It is definitely Neanderthaloid and must have acquired its peculiar cerebral characters independently of Homo sapiens by convergent development. Nor must the condition be regarded as a normal precocity of the Neanderthal child that afterwards atrophies. child's skull found at La Quina in 1921 by Dr. Henri Martin conforms in every respect to the adult Nean-Particular emphasis is laid in Dr. derthal type. Martin's and Prof. Anthony's reports upon the defective development of the frontal region.

The peculiar form of the Devil's Tower skull is, however, influenced to some extent by the age of the child, for it presents a certain analogy to the peculiarities often found in the five-year-old child of *Homo sapiens*. The chief interest of the endocranial cast of the Devil's Tower skull is the demonstration it affords that Neanderthal man reveals indications of possibilities in cerebral development formerly supposed to be the exclusive privilege of *Homo sapiens*.

# Structure and Formation of Colloidal Particles.

THE joint discussion between the Sections of Physics and Chemistry held on Sept. 2 at the meeting of the British Association at Leeds on the subject of the structure of colloidal particles, directed attention to the remarkable progress which has been made in recent years in the elucidation of the texture of disperse systems.

Both Sir William Bragg, who presided, and also Dr Freundlich laid emphasis on the importance of the method of examination by means of X-rays as well as on the limitations of the method. If the particles of a colloid are crystalline but not orientated in any specific direction, such as in gold and silver sols dispersed in water, a characteristic line photograph is obtained, whilst in addition, if the particles are orientated round an axis, as is the case in certain fibres, a spot pattern photograph is obtained. In many cases it is found that the broad diffuse rings indicating an amorphous character are replaced by the line photograph of the crystalline material as the suspension grows older, and we thus obtain a convenient method for determining the velocity of crystallisation of these substances.

When X-ray photographs are taken of liquids, it is found that in certain liquids, for example, cyclohexane, the rings are much more distinct and sharply bounded than in others; similarly, in the photographs taken of iron, prepared for the synthesis of ammonia by the catalytic method, both broad and thin rings can be obtained dependent on the method of preparation and the period of sintering. It is clear that we are dealing with materials which have a tendency to orientate themselves to form crystal nuclei.

It is somewhat unfortunate that the measurement of the breadth and intensity of the lines alone does not allow us to distinguish between two effects, whether the change in line breadth and intensity is associated with a change in the size of the nucro-crystals or a growth in the number of orientated particles. At the present time a method of distinguishing between these two factors is a matter of some importance.

Whilst the X-ray method alone gives no definite clue to the shape of the particle, it does at least give some indication of the processes by which crystals grow more readily in certain directions than in others, thus, the lamellar or flake-like character of large crystals of the fatty acids is readily anticipated from the crystal form determined by this method. Since, however, the shape of the particles is defined by magnitudes although submicroscopic yet greater than molecular in size, we may obtain information on this point by optical methods. A distinction between spherical and non-spherical particles can readily be made by observance of the scintillations in the ultra microscope or the double refraction of light in sols streaming through a channel, and even by the light absorption of colloidal solutions; thus, many sols, such as arsenious trisulphide and non-stretched gelatine, are found to be spherical.

The optical behaviour of streaming sols in a Tyndall beam gives some indication of the shape of the particles when these are not spherical; thus, it is possible to distinguish between attenuated string or rod-like particles in contrast to those plate-like or lamellar in form. The optical evidence for the rod-like structure of the colloidal particles of sols such as benzopurpurin or vanadium pentoxide is again supported by the shape of the macro crystals of these materials grown in the ordinary way. It is, indeed,

stated in the literature that benzopurpurin crystals can be grown so long and slender that they will pass through the pores in a filter paper in their end-on position, and that the crystals themselves are in continuous flexion under the influence of the Brownian agitation.

It is somewhat remarkable that the crystals of silver sols, which from their crystal growth one might reasonably anticipate to be either octahedral or possibly cubic in form, actually appear to deviate from the regular structure towards a lamellar form.

Such optical methods provide weapons with which the problem of the mechanism of formation of colloidal particles can be attacked. Von Weimarn's well-known criterion of the magnitude of the dispersion coefficient permits the prediction of the form of an insoluble product formed by interaction of two soluble salts. In cases where the dispersion coefficient is high, colloidal solutions or even gels may be obtained: the individual particle size is partly determined by the dispersion coefficient and the growth rate may be termed, with Haber, the grouping velocity. The clusters or aggregates of molecules thus formed at haphazard must, in order to become a crystalline assemblage, become orientated in their space lattices. This action may proceed at various rates; the velocity of orientation may be, and frequently is, very different from the grouping velocity.

It is thus possible to prepare numerous colloids, both in the crystalline as well as the amorphous state, by suitable adjustment of these two velocities. By rapid condensation of silver vapour admixed with naphthalene at liquid air temperature, for example, the preparation of colloidal amorphous silver can be effected, whilst under the ordinary conditions for preparing both colloidal silver or gold, the particles are completely crystalline, an indication that the velocity of orientation is extremely high.

These changes from the amorphous to the crystalline in solid substances can thus take place at different rates and are at least to a certain extent under control; that mechanical effects, such as stretching or pressure, effect orientation of the cell units in substances as varied as rubber, gelatine, and waxes, is definitely revealed by X-ray examination. An equally complex but interesting field for study is the structure of aerosols or smokes. As was pointed out by Prof. Whytlaw-Gray, the study of smokes is rendered more difficult by the fact that smokes are unstable and continue to undergo processes of aggregation and precipitation. Nevertheless, from photomicrographs it is possible to recognise definite crystal structure in many of such aggregates: in others the smoke particles appear as small spheres. It is at present a matter of interesting speculation whether the conceptions of von Weimarn and Haber on the conditions of formation of particles in solutions are not applicable in this field also

It is frequently argued that problems such as the shape or form of colloid particles may be a matter of deep scientific interest, but that the industrial chemist is satisfied provided that his suspension or smoke fulfils certain standard arbitrary tests, for example, grain size. A brief consideration of the relatively great covering powers of plate-like particles in paints and glazes, or the factors governing the adhesion of fungicides, to mention but two cases, shows that the discussion held at Leeds was full of import to numerous industries.

ERIC K. RIDEAL.

# University and Educational Intelligence.

CAMBRIDGE.- -Prof. A. S. Eddington has been elected as a member of the Council of the Senate. Mr. F. H. Garner has been appointed University

demonstrator in agriculture.

The annual report of the Board of Research Studies makes interesting reading. There have been 72 degrees of Ph.D. awarded during the year, 5 of M.Sc., and 6 of M.Litt. A third of the 272 resident research students are now graduates of Cambridge; the other English universities send 37 research students, the United States 31, Scotland 21, Australia 17, Wales 16, Canada 12, and South Africa 10. As to subjects, chemistry has 42 students, physics 35, mathematics 25, English 21, history 20, while divinity, geography, fine arts, metallurgy, and moral science claim but one student each. Trinity has now a strong lead in the number of research students with 46, followed by Emmanuel, 37; Caius, 25; and Newnham, 21; at the other end of the list are Peterhouse, 3; Pembroke, 2; Jesus, 2; and Selwyn, 3.

MANCHESTER.—Mr. T. H. Osgood has been appointed an assistant lecturer in physics.

The Council has appointed Prof. A. H. Gibson to represent the University at the celebration of the centenary of the Institution of Civil Engineers.

The following awards have been made: Grisedale biological scholarship in botany to Frances L. Stephens; William Kirtley senior scholarship in engineering to Frank Roberts.

THE degree of doctor honoris causa of the University of Paris has been conferred on Sir Frederic Kenyon, Director of the British Museum, and Prof. J. S. E Townsend, Wykoham professor of physics in the University of Oxford

THE third annual report, for 1926-27, of the London School of Hygiene and Tropical Medicine, was presented to the Court of Governors, which met on Oct 31. The Director, Dr. Andrew Balfour, reported on the work of the Tropical Division, and stated that the advantages of the twenty weeks' course of study in tropical medicine and hygiene, as compared with the shorter course, have now been definitely established. A Division of Medical Zoology has been constituted for administrative purposes, comprising the three Departments of Entomology, Helminthology, and Protozoology, with Prof. R. T. Leiper as its head. The organisation of the Museum continues to make steady progress under the immediate direction of Major-General Sır Wilfred Beveridge. Prof. W. W. C. Topley has been appointed to the chair of bacteriology and immunology, and is conducting a course of instruction for the newly instituted Diploma in Bacteriology of the University of London. The construction of the new building for the School, delayed by the coal dispute of last year, is now making substantial progress The provision of clinical and pathological facilities for the study of tropical diseases has been considered by a committee, which recommends the establishment, adjacent to the School, of a hospital with 150 beds, for which a capital sum of £250,000 would be The financial account for the year shows necessarv. an unexpended balance of £1452. The Trustees of the Rockefeller Foundation have now transmitted the whole amount of their original gift of two million dollars, which has been converted into sterling at a favourable rate. The University Grants Committee has notified that the grant of £7200 for 1926-27 has been increased, with the consent of the Treasury, to £18,000 for the new year.

An address on the future of technical education was delivered by the President of the Board of Education on Oct 19 at the Wigan Mining and Technical College. Two points were specially emphasised · the importance of guidance in the shape of specifications deliberately formulated by industrialists of what kinds of skill they wish to find in the recruits they are to draw from the technical schools, and the importance of mcreasing the day classes, which at present have very few pupils compared with the evening classes. As regards the first point, such specifications should provide for technical education the same kind of help as the secondary schools and universities receive, and have, for generations past, received from the pro-fessions. Much attention has been given to this matter during the past two years in the United States, where more than six hundred 'job specifications were drawn up a year ago by twenty-five of the largest industrial concerns in the country. Lord Eustace Percy hopes that with increasing definiteness of aim, technical education will be susceptible of more effective advertisement than is possible at present and will, in consequence, obtain more support. He attaches much importance to this task of "making a more or less clear picture out of the kaleidoscope of technical education." Referring to the need of more day classes, he pointed out that whereas about ninety per cent. of all our technical education is conducted in evening classes, about eighty per cent. in Prussia is in classes which do not meet after eight o'clock in the evening In Germany likewise, employers of labour commonly make attendance by their employees at day classes obligatory.

In the course of a recent discussion of "Technical and Non-technical Management" by the British Section of the Société des Ingénieurs Civils de France, an interesting account of technical education in France was contributed by Mr. Androuin and the reader of the paper, Mr. Lucien A. Legros. It would appear that a great deal of attention is being devoted to the improvement of apprenticeship. Certain works, such as those of Panhard and Levassor, make special arrangements for the training of their apprentices, for which purpose the older employees are engaged in providing an intensive training in pattern making, machining, and fitting. The value of the instruction is increased since the work performed is on parts which are actually required in the factory in small quantities. Technical instruction in France is given in public, national, and municipal schools. Private schools work in association with, or model themselves on, the State schools, and if efficient they are assisted by the Ministerial Department of Technical Education, which is said to be one of the best managed of State institutions. In all the schools the aim is to provide a thorough groundwork, on which specialised training can afterwards be developed. The Polytechnic, the Schools of Mines, of Bridges and Highways, of Posts and Telegraphs, etc., are very well known and have been founded to supply engineers for the Government services. In addition, there are numerous important technical colleges and specialised schools. In all the industrial schools a certain amount of commercial training is prescribed, while industrial technology is taught in the commercial colleges. In the Écoles des Arts et Métiers, instruction is given in both theory and practice. Third-year students are sometimes made charge-hands over small groups of other students, and this has proved so successful that steps are being taken to extend the practice. Students are also instructed in the making of drawings, and in estimating and preparing cost cards for various parts ordered by manufacturers.

# Calendar of Discovery and Invention.

November 13, 1807.—The mangural meeting of the Geological Society was held at the Freemasons' Tavem, Great Queen Street, on Nov 13, 1807. Among the eleven gentlemen present were Davy, Babington, Count Bournon, Greenough, William Allen, and Richard Phillips At this meeting a resolution was passed "That there be forthwith instituted a Geological Society, for the purpose of making geologists acquainted with each other, of stimulating their zeal, of inducing them to adopt one nomenclature, of facilitating the communication of new facts, and of ascertaining what is known of their science, and what remains to be discovered."

November 14, 1894.—Ten years after Sir Charles Parsons patented his steam turbine, the pioneer steam turbine vessel *Turbinia* was constructed on the Tyne, and on Nov. 14, 1894, carried out her preliminary trial. The *Turbinia* was 100 feet long and 441 tons displacement. Her first engine was a single radial flow turbine giving 960 h.p. at 2400 r.p.m., but this was afterwards replaced by three turbines developing 2000 h.p. and giving the vessel the extraordinary speed of 341 knots. The after part of the vessel and both sets of machinery have recently been presented to the Science Museum,

November 15, 1850.—In the ring of Saturn, first observed by Gahleo, can be distinguished three rings, an outer ring called A, a middle ring B, and an inner ring C. This inner, or dusky ring, some 11,000 miles across, was first distinguished by Bond on Nov. 15, 1850

November 16, 1492—In the parish church of Ensishem in Alsace hangs the oldest known meteorite. Of this a contemporary document says, "On the 16th of November 1492, a singular miracle happened; for between eleven and twelve in the forenoon, with a loud crash of thunder and a prolonged noise, there fell in the town of Ensishem a stone weighing 260 pounds. . . It was taken to the church as being a miraculous object."

November 17, 1893.—Heaviside's writings are contained in his "Electrical Papers," covering the period 1872 to 1892, and his "Electro-magnetic Theory" containing his work up to 1912. In the latter is his historic paper of Nov. 17, 1893, in which he laid down the principles of the use of inductance coils in telephone circuits.

November 18, 1846.—Sulphuric ether had been known in the thirteenth century. It was recommended as an inhalant for asthma by Pearson of Birmingham in 1785, and it is said that Faraday in 1818 noted the effects of inhaling it. It was Prof. Jackson of Harvard who suggested to W. T. G. Morton the possibilities of other as an anesthetic, and on Oct. 16, 1846. Morton successfully administered it to a patient in the General Hospital of Boston, while the discovery was made known to the world by Dr. Bigelow on Nov. 18, 1846.

November 19, 1787.—"The advance of astronomy m the eighteenth century," wrote Miss Clerke, "ran in general an even and logical course. The age succeeding Newton's had for its special task to demonstrate the universal validity, and trace the complex results of the law of gravitation. The accomplishment of that task occupied just one hundred years. It was virtually brought to a close when Laplace explained to the French Academy, November 19, 1787, the cause of the moon's accelerated motion "With this work, says another writer, "the last anomaly and the last threat of stability thus disappeared from the solar system" E. C. S.

Royal Society, Nov. 3.—Hans Spemann (Crooman Lecture): Organisers in animal development. The conception of 'organisers in development' has been derived from experiments in amphibian embryos in the earliest stages The different regions of such an embryo have not the same value for development. most of them are relatively indifferent and do not carry their destiny in themselves. This can be shown by transplantation of these parts into other regions of the embryo; they follow the development of their new environments. But there is a certain region in the embryo, parts of which, when transplanted into an indifferent region of the embryo, do not adapt themselves to their new environment, but retain their own character, and force, as it were, the others to follow them Such parts organise a new embryo, which is built up partly by the transplanted cells, partly by the cells of the host. Therefore they were called 'organisers,' and the region where they he together in those early stages of development the 'centre of organisation.' Further experiments have been made to determine the extent of this centre, its origin, its intimate structure, and the nature of the organising influence

# WASHINGTON, D.C.

National Academy of Sciences (Proc., Vol 13, No. 9, September). -E. S. Castle: The interrelation of the eyes of Palæmonetes as concerns retinal pigment inigration. Plaster of Paris and lampblack makes a harmless eye covering, and in Palæmonetes with one or both eyes covered, the pigment in the covered organ takes up the position occupied by the pigment of eyes adapted to darkness. Leaving one eve uncovered does not affect pigment movement in the covered eye.—Henry Federighi. The blood-vessels of annelids. Annelid blood-vessels generally and vertebrate capillaries are similar both histologically and physiologically. Both consist of an endothelium with a layer of isolated cells. In Nereis wrens, contraction of contractile vessels is independent of central nervous control and is of two types, (a) peristaltic, due to the endothelium; (b) local, due to the isolated cells (Musketzellen) and actuated by direct stimulation.—Jan Schilt: The effect of a rotation of the galaxy on proper motions in right ascension and declination B Knaster and C. Kuratowski - Remark on a theorem of R. L. Moore. The theorem refers to indecomposable continua. Gordon T. Whyburn Concerning the open subsets of a plane continuous curve.—S Lefschetz. On the functional independence of ratios of theta functions. -E. (' Watson and J A. Van den Akker: The direction of ejection of X-ray electrons. Magnetic spectra of the electrons ejected by X-rays from exceedingly thm metallic films show that the most probable direction of ejection is a little forward of perpendicular to the direction of the X-ray beam and is the same whatever level in the atom the electron comes from and whether the absorption energy is large or small. It is difficult to explain these results if the electronic orbits are regarded as having physical reality -William Duane: The character of the general, or continuous spectrum radiation Electrons from a hot wire cathode were shot into a stream of mercury vapour at very low pressure and the radiation produced by impacts of electrons and mercury atoms was observed by an ionisation chamber. The voltage applied to the tube was less than 12,000 volts (the  $\hat{L}$ -series of mercury require at least 12,300 volts and any M-series radiations were absorbed), so only general radiation was measured. Under these conditions, with many impacts, the electron transfers almost all, if not all, of its kinetic energy to the quantum of radiation produced, which appears to be very nearly mono-

chromatic -- G. H Dieke and Harold D. Babcock The structure of the atmospheric absorption bands of oxygen. - Charles E. St. John: Revision of Rowland's preliminary tables of solar spectrum wave-lengths. The starting point of Rowland's system (1893) was the mean wave-length of the  $D_1$  line of sodium as referred to the standard metre by five observers. In 1893, Michelson and Benoit, and in 1907, Benoit, Fabry, and Perot, using a Michelson interferometer, obtained the absolute wave-length of the red cadmium line in terms of the mètre des achives, and this was adopted as the primary standard in the international system of wave-lengths system of wave-lengths For many years now, measurements have been made at Mount Wilson, one series utilising simultaneous exposures to the centre of the sun and the standard iron are with the 30 ft and, later, the 75 ft. spectrograph, and the other interferometer measurements, and the results corrected for the rotation and orbital motion of the earth The results are to be issued shortly by the Carnegie Institution of Washington as a "Preliminary Table of Solar Spectrum Wave-lengths."—George de Thierry Application of the law of similitude to hydraulic laboratory research -A. Keith Brewer: Some factors influencing the ignition of carbon monoxide and oxygen. The ignition point of an explosive mixture of carbon monoxide and oxygen, using a condensed discharge, is, at constant pressure, determined by the energy of the spark, while at different pressures the ignition points are related as the voltage. Water vapour as an impurity lowers the ignition point, the merest trace enabling the reaction to proceed to completion, whereas in the dried mixture there was seldom more than 10 per cent. completion. Other impurities may be (1) mert except that they absorb energy, increasing the ignition potential (introgen, carbon dioxide, chloroform, alcohol, etc.), or (2) oxidised in the explosion and thus lower the ignution potential (water, hydrogen, alcohol, carbon disulphide, etc.). The effect of alcohol depends on the amount of oxygen present. It is suggested that the lowering of ignition potential is brought about by the catalytic activity of 'new-born' decomposition products of the impurity.

# Evolution and Theology.

THE recently published correspondence between the Bishop of Birmingham and the Archbishop of Canterbury has not been without interest for students of the natural sciences, since it sheds some light upon the attitude of the authorities of the English Church towards the results of scientific research. We are of course not concerned in these columns with spiritual faith or denominational belief, but it is appropriate to make clear the attitude now presented by leaders in the Church towards progressive scientific knowledge, and the best method of doing this may be to quote certain relevant passages from the correspondence in In parenthesis, and as a sign of the new spirit which now prevails between leading representatives of science and theology, it is sufficient to mention that Sir Arthur Keith, president of the British Association, is to take the chair on Monday next at a lecture to be delivered by Dean Inge on the subject of "Scientific Ethics."

Dr. Barnes's first letter to the Archbishop, occasioned by the outburst at St. Paul's Cathedral on Oct. 16, contains the following observations:

"One cause of the weakness of the Church has arisen from the apparent determination of teachers to ignore scientific discovery. Though all competent biologists accept man's evolution from an ape-like stock, the theological consequences of such belief are still seldom stated. I set myself years ago to expound these consequences and to show why they did not seem to me to upset the main Christian position."

To this the Archbishop replied that the Bishop was disturbing himself unnecessarily, since evolutionary views had won wide acceptance amongst religious people, and were now no novelty

"I believe that you overrate the adherence of thoughtful people to creation theories of fifty to a hundred years ago, and I scarcely think that among those who listen to you there are a great number who hold the opinions which you satirise. For myself, at least, I can say that your position on the biological question, in outline and so far as I understand it, is one with which I personally have been familiar for more than fifty years. Believe me, this teaching, however admirable, is to most of us not novel"

Although these remarks may be said to have evaded the issue raised by Dr. Barnes, yet they constitute a valuable pronouncement, admitting as they do the theological legitimacy of evolutionary opinions, and they were immediately welcomed as such by Dr. Barnes in his reply.

"I would publicly thank your Grace for your letter in answer to my own. By tacit acknow-

ledgment of the truth of the biological doctrine of evolution your Grace removes from Christian ministers of our Church any qualms in proclaiming it"

Dr Barnes then returned to the point alluded to in his former letter, a point which the Archbishop had allowed to escape him

"Of course in my sermons I have sought to emphasise not so much the doctrine itself as the readjustments of Christian dogma consequent upon its acceptance."

Since no official reply has been published to this further letter of the Bishop of Birmingham, the Council of the Churchmen's Union, a body of theological liberals under the presidentship of the Very Rev. Dr. Inge, Dean of St. Paul's, dispatched a letter to Dr. Barnes, which contained the following remarks

"You are blamed for preaching evolution to general congregations Now it is true that the accepted teaching of science on this subject has long been familiar to educated people who find no difficulty in reconciling it with the Christian faith. But the acceptance of evolution as a biological theory is often unaccompanied by any attempt to follow up the consequences of the theory in their bearing on traditional theological statements, and we believe that in making the attempt you are doing good service which is greatly needed at the present time"

The correspondence from which the foregoing extracts have been given seems to indicate a somewhat anomalous state of affairs. While biological theories of the evolutionary origin of man, and indeed of creation generally, appear to prevail among educated members of the Church of England, clerical as well as lay, no systematic attempt is being visibly made to modify the traditional dogmatic system in view of the new knowledge which radically affects it.

The pressing nature of the need for such theological restatement in view of knowledge which, as the Archbishop reminds us, is fifty years old, can escape no reflective person. We have only to consider how integral to the traditional dogmatic system is the doctrine of a historical fall of man. The Christian theory of human nature (that is, its need of supernatural grace, and so on) hangs upon it, while the scheme of redemption, involving a historical incarnation, is its dogmatic correlative. It is not merely a question of the earth having been created in six days or during incalculable periods of time—that issue, though it has been considered serious, is trifling compared with the others raised by the theory of evolution.

There has, of course, been much literature published dealing with different aspects of the subject.

Dr N P. Williams, the Regius professor of divinity at Oxford, devoted his recent "Bampton Lectures" to a historical and philosophical treatment of the doctrine of original sin, a book characterised, as Prof W. R. Matthews has observed, by "its frank acceptance of modern views of the world and its repudiation of ideas which have long been accepted in the Church" Canon Streeter also, in his book "Reality" (1926), includes some remarkably stimulating chapters which deal quite frankly with the problems of man's relation to Nature, and, above all, of the problem of evil—of which the Genesis myth is an attempted solution. This problem, which is so radically affected by evolutionary theories, Canon Streeter rightly regards as more. important than any other for religion Thus evolution touches the very heart of religion, and cannot be disregarded by religious teachers who take their task seriously.

If we may be permitted another example, it may be found in Dr. Major's "English Modernism," a work which contains lectures recently delivered at Harvard. Dealing with new ideas of creation, he registers "the acceptance of evolution as the Divine creative method, and the abandonment of instantaneous creation by successive Divine flats", and he observes that this "entails the acceptance of the fact that the creative process is still proceeding." This view, "although it seems modern, appears to underlie the theology of the Fourth Gospel," and is also in harmony with the remarkable passage in the eighth chapter of Romans, where creation is spoken of as still travailing in birth-pangs.

Yet in spite of these and other sincere and able efforts to find a new expression of Christian truth in terms of evolutionary science and philosophy, it seems to be widely held in authoritative circles (1) that the new doctrinal view should be disseminated only with extreme caution and reserve, and (2) that restatements of dogma would at present be highly. dangerous. It would seem to be against this overcautious policy that Dr. Barnes is in revolt. In advocating the bolder course, he will certainly have the sympathy of men of science, who are quite accustomed to frank restatements of doctrine; indeed, science has progressed by means of them As for the fears expressed for the faith of the weaker brethren, a remark made many years ago by Prof. Harald Hoffding seems apposite:

"No one wants to rob the poor man of his ewe lamb—only let him remember that he must not drive it along the high road unnecessarily and then demand that the traffic should be stopped on its account."

# History of Medicine.

An Introduction to the History of Medicine from the Time of the Pharaohs to the end of the XVIIIth Century By Dr. C. G Cumston With an Essay on the Relation of History and Philosophy to Medicine, by Dr F. G. Crookshank. (The History of Civilization Series) Pp. xxxii + 390 + 24 plates. (London: Kegan Paul and Co., Ltd, New York: Alfred A. Knopf, 1926) 16s net.

WE welcome the appearance of a work on the history of medicine by Dr C. G. Cumston, who, in addition to other qualifications for the task, was president of the fifth International Congress of the History of Medicine held at Geneva in July 1925 (see NATURE, Nov. 14, 1925, p. 729).

The book is divided into twenty-one chapters, in which the writer successively discusses Egyptian medicine, Hindu medicine, Greek and Roman medicine, Islamic medicine, medicine including physiology, anatomy, pathology, nosology, therapeutics, and surgery in the sixteenth and seventeenth centuries, and the principal medical doctrines of the seventeenth and eighteenth centuries A special chapter is devoted to the doctrine of irritability, the Brunonian theory, and naturalism, and another to organicism and vitalism. The concluding chapter consists of a brief survey of the evolution of therapeutics.

After an introductory chapter on the evolution of medicine, showing how it gradually advanced through the theological and metaphysical stages before reaching the positive stage described by Comte, Dr Cumston devotes a chapter to Egyptian medicine, in which he shows how the history of the healing art is to be found in the various papyri. The following chapter on Hindu medicine contains numerous quotations from the Vedas relating to medicine, such as the account of the birth of the Hindu Æsculapius, the duties of the playsician and nurse, plastic operations, and the legend of Jivaka, which shows that the operations of major surgery were at least known if not actually carried out by the ancient Hindus. The next chapters deal with Greek medicine, commencing with the philosophers, such as Theophrastus, Pythagoras, Heraclitus, Parmenides, Alcmæon, Empedocles, and Diogenes of Apollonia. A special chapter is devoted to the Hippocratic oath, which has always been the guide of the medical profession. In the following chapter, which is concerned with Hippocrates and the Hippocratic Collection, Dr. Cumston points out that naturalism was created from the time that Hippocrates demonstrated the existence of a formative, conservative, and medicative power inherent in the organism, by which it feels, reacts, and develops, preserves itself, and combats morbid causes and the effects produced by them

Among the direct successors of Hippocrates, with whom the next chapter deals, may be mentioned Aristotle and his disciple Theophrastus, who contributed indirectly to the progress of medicine by their studies in natural history, Diocles of Carystus, who was one of the first to make a scientific study of anatomy, and Praxagoras of Cos, who was one of the last of the Asclepiadæ whose name has been preserved. More importance, however, attaches to the school of Alexandria, of which Erasistratus and Herophilus were the most illustrious representatives, as it was from this school that the systematic study of anatomy emanated

An interesting survey is given in the succeeding chapters of medicine in ancient Rome, including the practice of Asclepiades, whose system was based on the teaching of Epicurus, the school of methodism founded by Themison and also represented by Thessalus, Athenæus of Cilicia, Archigenes of Apameia, Soranus, the author of a work on diseases of women, and Cælius Aurelianus, who wrote on acute and chronic diseases. The chapter on Galen contains an instructive comparison between him and Hippocrates. According to Dr. Cumston, Galen would certainly have equalled the father of medicine if he had had less imagination and independence of character, and had not been influenced by the philosophy of Aristotle. Galen explained facts by hypotheses, whereas Hippocrates observed the phenomena of Nature without explaining them. The result has been that the doctrine of Hippocrates has survived, but Galen's system of medicine has been completely destroyed.

In the chapter on Islamic medicine, Dr. Cumston controverts the view that the Arabians were merely servile copyists of the Greeks, and maintains that in addition to their methodical classification of the scattered elements of Greek medicine they created clinical medicine and enriched pathology with a knowledge of new diseases.

The medical schools of Salerno and Montpellier next receive attention, an interesting description being given of Trotula, Constantine the African, the Regimen Sanitatis, Roger of Parma, Guy de Chauliac, Sylvius, and Rabelais.

The chapters on medicine in the sixteenth century contain an account of the work of Jean Fernel, the author of "Universa Medicina"; Fracastor, the first scientific writer on the doctrine

of contagion and author of the celebrated poem on syphilis; Paracelsus, who helped in the advancement of medicine by introducing mineral substances into the therapeutics; and the great Italian anatomists. In discussing the medical doctrines of the seventeenth century, Dr. Cumston maintains that the three great contemporary schools of medicine, namely, the iatro-chemical, iatro-mechanical and vitalistic, and animistic schools, owed their existence to the three great philosophers Van Helmont, Descartes, and Leibnitz.

Dr. Cumston distinguishes three periods in the eighteenth century to illustrate the progress made in anatomy and physiology. The first period was that of direct continuation of the researches carried out during the seventeenth century, and was represented by Littré, Duverney, Verheyen, and especially Winslow and Sénac, who discovered the muscular fibres and valves of the heart. The second period was represented by Albrecht von Haller, who published his work on sensibility and irritability in 1752, while the third period, which covered the last twenty-five years of the eighteenth century, was remarkable for the discoveries of Lavoisier, Fontana, Priestley, Fischer, Vauquelin, and Abernethy.

Dr. Cumston may be congratulated on having succeeded in presenting the general reader and student of medicine, for whom the work is intended, with an admirably clear and thoughtful introduction to the study of medical history. The text is accompanied by excellent portraits and other illustrations, most of which are from the author's private collection.

# Australian and New Zealand Insects.

The Insects of Australia and New Zealand. By Dr. R. J. Tillyard. Pp. xin + 560 + 44 plates. (Sydney: Angus and Robertson, Ltd.; London. Australian Book Co., 1926.) 42s.

THE curious and beautiful insect fauna of Australia is perhaps the most attractive in the world. That of New Zealand, notwithstanding certain features of special interest, is on the whole rather disappointing and very defective, but its treatment in conjunction with the Australian relieves this difficulty. Both faunas are now so far known as to admit of their general features being set forth in a text-book, and also so far unknown as to offer a marvellous field for exploration to those possessed of such a guide The appearance of this volume, which is intended both for university students and for amateur naturalists, is well

timed, and it should cause a large expansion of local study

A full and lucid account is given of the general structure of insects, and the modifications characterising the twenty-four orders in which they are classed, illustrated by numerous clear and excellent drawings This, the most important part of the work, is also the best, and can be recommended to entomological students of any country, the fundamental details of the wing-neuration in particular are thoroughly explained. The broad lines of the scheme of classification employed are reasonable and intelligible. The characters of the orders are tabulated in the form of a general conspectus, and in each order the analysis is carried down to families by dichotomous keys. hence an unassisted student should find himself able to refer any insect to its proper family This method of procedure so much assists comprehension and saves so much time that it is unavoidable; but all who use such keys should be made aware that they can only be generally and not absolutely correct; exceptions are continually being discovered, and nothing in Nature is constant. Undoubtedly learners, especially when dull, like to have cut-and-dried formulæ, but they had better face the truth. They will also find that reliance on any single character is always risky. and that affinities must be judged by the sum of all characters, if they are to be natural

When we examine the internal arrangement of the orders, some errors are perceptible. Taking the Lepidoptera as an example, the butterflies are still classed as a separate division, Rhopalocera, equivalent in value to all the rest of the order except the primitive Jugata (Comstock's group, quite unnecessarily renamed by Dr Tillyard Homoneura), though the case is really given away on p. 455, where the probable relationship to the Pyraloid groups is admitted The definitely conclusive argument is, however, that when all other groups are considered separately, all are found alike impossible as ancestors of the butterflies, except the Pyraloids alone. Most authorities would also probably now admit that the skippers (Hesperiadæ) are not really from the same stock as the other butterflies, but from a related and more primitive one, the antennal club and loss of frenulum being adaptive characters and developed independently in each case. Again, the small jugal lobe quite correctly mentioned as present in early forms of Nepticulidæ (discovered by Miss Braun) might have warned the author that these highly interesting little insects (with quite unique

neuration) cannot possibly be degraded Tineoids; they are an original development from Micropterygidæ, and must form a separate primary division; their universal distribution is part of their antiquity. The singular little Epipyropidæ, confined to Australia, the larvæ of which are parasitic on Hemiptera, cannot be included among the Tineoidea, the neuration, absence of palpi and tibial spurs, and all other characters refer them to the Psychoidea, certain forms of which they closely resemble. Nor does the inclusion of the Drepandæ in the Noctuoidea seem to have any other merit than that of novelty, the type of neuration approximates to the Pyraloid.

Under each family are given some few details of striking or interesting species, and there are coloured and plain plates acquainting the student with the general aspect of many of these, which are probably intended to stimulate popular interest. These items of general information appear sometimes untrustworthy. Corrections under the Lepidoptera should be made as follows: Tinea fuscipunctella is not a clothes-moth, but a refusefeeder; the similar clothes-moth is T. pellionella. Ephestia cautella is certainly not identical with E. kuehniella, the so-called 'Mediterranean Flourmoth', it is the species formerly known as cahiritella Guen The attribution of Lysiphragma to the Elachistidæ, even in the wide sense (out-ofdate) in which this term is used, is quite unintelligible and cannot be intended; it is a true Tineid. The decaying family Copromorphidæ are twice stated to be confined to Australia and New Zealand; but even the first species ever described was from Fiji, and others have been recorded from the Papuan and Malayan regions, India, S. Africa, and S. America. The character by which this family is separated from several others in the key (presence of cubital pecten in hindwings) fails to operate. as the same structure occurs fairly frequently in one of them, the Gelechiadæ, for example in Dichomeris. It may also be noted that the characteristic compression of the third segment (terminal joint) of palpi in Glyphipterygidæ is not lateral but transverse.

It is gratifying that Dr. Tillyard has attempted to preserve orthography in nomenclature. Such forms, however, as Sericostomatidæ, Selidosematidæ (formed from Sericostoma, Selidosema), are really new errors, based upon the old error (corrected in Nature, vol. 41, p. 342, 1890) that such generic names are neuter substantives, whereas they are feminine adjectives; the stem of the Greek stoma is stomat-, but of Sericostoma

It is Sericostom. Another barbarism adopted from Hampson is that of the use of the terms Trifinæ and Quadrifinæ for the divisions of the Noctuoids called by Guenée quite correctly Trifidæ and Quadrifidæ; presumably on the supposition that -idæ is a family termination and therefore inappropriate, whereas -id- is of course part of the stem (fid-, denoting fission), and if the termination -inæ is desired, the correct terms would be Trifidinæ and Quadrifidinæ

Finally, in an interesting chapter on the geological history, Dr. Tillyard states his views on the origin of these two faunas. It is impossible to discuss them here; a long article would be required even to recite the difficulties that arise on their consideration. Why, for example, if both New Zealand and Tasmania were successively connected with Antarctica, should there be fifty species of Crambus (the origin of which must certainly have been thence) in New Zealand and none in Tasmania? More probably Tasmania was never so connected. We must leave such problems to be investigated by some of the philosophers who are to be called forth by this useful volume

Edward Meyrick.

# Science and Art of the Dyer and Colourist.

- (1) The Dyeing of Textile Fibres. By R S. Horsfall and L G. Lawrie. Pp. x +415 (London: Ernest Benn, Ltd., 1927.) 28s net.
- (2) The Dyeing of Cotton Fabrics. By Franklin Beech. Third edition, revised and enlarged by A. J. Hall. Pp xii+296. (London: Ernest Benn, Ltd., 1927) 18s net.
- (3) Textile Colour Mixing · a Manual intended for the Use of Dyers, Calico Printers and Colour Chemists. By David Paterson. Third revised edition. Pp. xiv+130+7 plates. (London: Ernest Benn, Ltd., 1927) 12s 6d net
- (1) TR. R. S HORSFALL and Mr. L. G. Lawrie, who are members of the staff of the British Dyestuffs Corporation, Ltd., the former being head of the dyehouse department of that firm, are peculiarly well-fitted for the compilation of a book dealing with the dyeing of textile fibres in general. The outlook of the average dyer must be limited largely to the activities within his own dyehouse, so that the types of dyeing upon which he is engaged and in which he is expert eventually become in his eyes the most important. As a result, although fitted to produce a specialised monograph dealing with the sections of the trade upon which he is engaged, he would be liable to produce an unevenly balanced general book on

dyeing. On the other hand, nowhere can such a varied experience of dyeing be gained as in the dvehouse section of a works where colouring matters are manufactured. It is here that colouring matters are submitted to the most rigorous examination in order to discover their good qualities or defects, and to elaborate the most suitable methods of application in the case of products of commercial value Further, the success of a colour works depends to a great extent upon close touch being maintained between the expert staff of its dyehouse section and all types of the colour consuming industries. Consequently, a most varied and evenly balanced experience of dyeing is gained, as is apparent in the book under review

The authors consider that most text-books attach more importance to dyestuffs than to the material to be dyed, with the result that the subject of dyeing the various fibres, cotton, bast fibres, artificial silk, wool, and natural silks, is approached through descriptions of the various classes of colouring matters. They have decided, therefore, to approach the subject from the angle of the material to be dyed, keeping in mind the manufacturing processes which the dyed material still has to undergo or the final uses to which it is to be put, with the view of simplifying the matter. Whether it is really a simplification to give excellent descriptions of machines without a single illustration, and to restrict the use of the formulæ of dyestuffs to the solitary example of aniline black, is open to debate, but that the authors have produced an outstanding book on dyeing cannot be questioned. It is written most attractively, and once its pages are opened it is difficult to lay it down unread. This thoroughly up-to-date book invites perusal and will be heartily welcomed by students of dyeing, whilst the general science reader who desires to know something of the science and art of dyeing as practised at present, can turn to no better source of information.

(2) Mr. A. J. Hall, on the other hand, has laid himself open to criticism in attempting to revise Mr. Franklin Beech's book. The first edition, published in 1901, described various processes and operations involved in dyeing cotton fabrics, from a practical and empirical point of view, rather than a scientific one, and may have been of service to evening students in technical schools at that date. Actually, the limited and unsatisfactory revision which has been carried out has altered the original character but little, whereas such drastic treatment as to render the original text unrecognisable

would have been necessary to convert this into a modern text-book. The publishers would be well advised to discard this book and arrange with Mr. Hall to write a new one

(3) Mr. David Paterson's well-known little book on colour mixing, in which he deals with his subject in a simple and practical manner, has proved a useful manual for elementary students since it first appeared in 1900 Although the original style has been preserved, the opportunity has been taken to revise the text somewhat without materially affecting its length. The dyed patterns used as illustrations of the text were dyed with German dyes in the first two editions, but are now dyed with colours of British manufacture, whilst further signs of the times are the increase in the price from 7s. 6d to 12s. 6d. since the second edition appeared in 1915, and the use of fewer coloured plates. Those engaged in the application of colouring matters cannot afford to neglect the subject of colour from a purely physical point of view. The first few chapters give an elementary account of colour, absorption spectra, and the spectroscope, and with this as a basis the remainder of the book deals practically with the mixing of lights, dyes, and pigments.

Although it is true that skill in dyeing and colour mixing cannot be acquired from books alone, knowledge such as can be acquired from the first and third of the books on this list is indispensable if young men are to cope with present-day conditions in the colour-using industries. F. M. Rowe.

### Cultivation of Sugar-Beet.

Handbuch der Zuckerrübenbaues. Unter Mitwirkung von Dr. A. Schaumburg. Bearbeitet von Prof. Dr. Theodor Roemer. Pp. v + 366 + 8 Tafeln. (Berlin: Paul Parey, 1927.) 19 gold marks

ANY considerable work dealing with the selection, culture, and manuring of sugar-beet is certain to arouse interest in England, now that our own sugar-growing industry is developing with such great speed. In some six years our area under the crop has increased from about 8000 to 126,000 acres, and even those farmers who have been growing it since the starting of the Cantly factory in 1910 must confess to a considerable ignorance of the principles underlying the cultivation and manuring of it. Recently, many inquiries on the subject have been addressed to the various centres of agricultural teaching and research, and there has been some difficulty in obtaining trustworthy information.

Dr. Roemer, with a full century of continental experience behind him, attacks the whole subject in a patient and thorough manner, and quotes the chapter and verse of laboratory and field experiments in support of most of his statements and recommendations

In the department of manuring he owes much to Schneidewind, several of whose opinions and experiments he quotes, while in the realm of cultivation he has drawn on the work of Wollny and a host of other continental workers In the matter of manuring, Dr Roemer stresses the fact that an excess of nitrogen and its late application leads to poverty of sugar content, delayed maturity and poor keeping quality, points which were well confirmed in an experiment at Rothamsted carried out only last year. In other particulars of manuring he recommends a moderate use of phosphate to ensure good texture in the root and to help maturity, and he thinks that a shortage of available potash leads certainly to a lowering of the sugar percentage in the root

In regard to spacing the roots in the field, Dr. Roemer favours a wider setting of the rows than most continental experts 20 in ×9 m. is the actual spacing that he names, and this compares curiously with the 14 in.  $\times 8$  in. and 16 in  $\times 8$  in. which have been recommended by many of the Dutch and German experts. Many British growers have objected to these very small spacings on the ground that it is practically impossible to use horse labour in the narrow rows, and that additional hand labour is very expensive and slow even when it is available. It is interesting to observe that Dr. Roemer supports his practical recommendation with a similar statement of labour difficulties in Germany. Throughout the book he makes great play with the necessity that exists for improved mechanisation • in the handling of the crop in the interests of speed and labour saving, and he has a number of interesting things to say about spacing drills, singling machines, and mechanical harvesters. In this last and very important particular he considers that the problem of mechanical harvesting of beet is now solved, and that we only wait for improvements of the existing machines

Taking the book on the whole, it appears as a very valuable addition to a section of agricultural literature which is not well represented in Great Britain, and it seems reasonable to expect that many of Dr. Roemer's conclusions will apply quite closely to sugar-beet growing in British conditions.

Spectroscopy. By Prof. E. C C. Baly. (Textbooks of Physical Chemistry) Third edition. In 4 volumes. Vol. 3. Pp. viii +532 +6 plates. (London: Longmans, Green and Co., Ltd, 1927.) 22s. 6d. net

The third volume of Prof. Baly's "Spectroscopy" has followed very quickly upon vol. 2, a review of which appeared in our issue of Aug. 6, p. 185. It includes only four chapters, on series of lines in spectra, on the Zeeman and Stark effects, and on emission band spectra, but, since the first of these chapters covers more than 300 pages, the volume is rather larger than its immediate predecessor volume starts inevitably with Balmer's discovery of the first spectral series in 1885, but records an evergrowing acceleration which must have made it very difficult for the author to leave off writing and let his work go to press In order to do justice to the work of the pioneer investigators, he has rejected the tempting option of beginning with Bohr's first application of the quantum theory to spectroscopy in 1913, and has told the complete story of the work done by Rydberg, Kayser, Runge, Paschen, Fowler, and Millikan in the period when experiment rather than theory was the order of the day.

The main portion of the volume, however, is necessarily based upon the Bohr theory and its developments; and those who have tried with only moderate success to grapple with these developments will appreciate the 'humbleness of mind' which the author admits in his preface. He has, nevertheless, been able to complete this portion of his task within a reasonable time, and may be congratulated on his success in dealing with a situation which he could not possibly have foreseen when in 1905 he wrote a single volume on spectroscopy for this important series of monographs. It is, indeed, a noteworthy fact that the task of keeping abreast with the most active section in pure physics should have fallen to the lot of a chemist, writing (under the editorship of a chemist) a text-book of physical chemistry, and that his courage and skill should have proved adequate to this formidable task

Hydro-Electric Handbook. By William P. Creager and Joel D. Justin, with the Assistance of nine Contributors Pp. xxiv + 897. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1927.) 40s. net.

A BOOK verging on 900 pages provides scope for much matter, and the designation "Handbook" rather inadequately describes the wealth of information which is to be found in the volume before us Although bearing the names of two authors, it is really a compendium by them and nine other contributors, covering in its thirty-five chapters almost every subject and topic connected with hydro-electric development works. It is essentially an engineering manual, based on the wide field of experience obtainable in North America, where water power is an important natural endowment and is being exploited for

industrial purposes on a scale of magnitude greatly exceeding anything that is feasible in Great Britain

The mere enumeration of chapter headings would occupy almost the whole of the space available for a short notice, and it is only possible to indicate a few of the more important items which are treated by the various writers. There is an introductory section on rainfall, evaporation, and run-off, illustrated from United States records, together with a description of methods of estimating stream and flood flow, with the resultant yield of data respecting storage and power available for development. A short résumé of principles of hydraulics is then followed by four chapters dealing with different types of dams, and thereafter come descriptions of various other constructional features and power-developing equipment, including turbines and generators, extending to power transmission lines.

In brief, the book is a very complete and concise summary, from the American viewpoint, of the theory and practice of water-power supply at the present day. It is excellently printed and produced. The diagrams also are clear, and in some instances are duplicated, so that one copy may be detached for pocket use.

BRYSSON CUNNINGHAM.

In Search of our Ancestors: an Attempt to retrace Man's Origin and Development from Later Ages back to their Beginnings. By Mary E. Boyle. Pp 287 + 4 plates (London, Bombay and Sydney. George G. Harrap and Co., Ltd., 1927.) 10s. 6d net

MISS BOYLE has reverted to the practice of a former day in archæological exposition by working backwards. Her search for our ancestors begins with the Iron Age and traces them back through the various stages of culture of metal and stone to Quaternary and Tertiary man with their coliths, and then to the earliest forms of life in the tertiary, secondary, and primary periods. The Abbé Breuil, in a foreword, commends the author's method of attack on the ground that it leads the student back ultimately to the principle of unity and the first cause. With all deference to so great an authority, we would dissent. In dealing with prehistoric culture, the sense of development, the evolutionary process, even as a 'way of knowledge' as the Abbé defines it, to a great extent is lost when we work back from the complex to the more simple.

Apart from this point of method, Miss Boyle's treatment of her subject is eminently skilful, and she has handled the mass of detail now available in a masterly fashion. She deals, however, in the main, with Europe only, and that from the cultural side. Ethnological questions are not taken into account. This no doubt must be held to account for some omissions and for the fact that references to Egypt and Africa are incidental only. Yet it is difficult to see why recent discoveries at Ur and Kish, important as they are for the early use of copper and bronze and their relation to the use of stone, are not mentioned, although there is an adequate summary of the evidence from Hissarlik.

Navigational Wireless By Dr S. H Long. Pp. x1+164+12 plates (London: Chapman and Hall, Ltd., 1927) 12s 6d net.

The scope of this book is not so comprehensive as the title suggests, since the book deals almost entirely with the application of wireless direction-finding to marine navigation, and the book is intended to provide mutual instruction to the wireless operator and to the navigating officer. After two introductory chapters on general electricity and the application of valves and methods of screening to wireless receivers, the principles of direction-finding and the various available systems are described. The next two chapters deal with the installation of the Siemens direction-finder on board ship and the calibration of the instrument to determine the quadrantal error curve due to the metalwork of the ship.

The navigational side of the subject is treated in chapters vii., viii, and ix, which describe the various charts necessary in plotting off bearings at sea, and the method of applying corrections to the charted bearings. In the following chapter a description is given of the various effects on wireless bearings encountered in practice, but here many of the results of recent research on the subject have been omitted. The necessity for the provision of beacon transmitting stations for the use of ship's direction-finders is mentioned in the concluding chapter, which also contains a brief description of some sound-signalling devices.

The book has been well produced with a large number of excellent photographs and diagrams, and only one or two misprints have been noticed.

R L S.-R.

Der Erde Eiszeit und Sintflut ihre Menschen, Tiere und Pflanzen. Von Dr. O Hauser. Pp. vii + 370 + 22 Tafeln + 2 Karten. (Berlin: George Stilke, 1927) 16 gold marks

For the layman who can read German, and is not deterred by Germanic characters, Dr. Hauser has provided an extremely interesting survey of early human types and history. The introductory chapters include a brief summary of historical geology and of the evolution of life forms. Considerable attention is given to the Wegener hypothesis of continental drift, the treatment leading up to a discussion of the 'new world' of the Tertiary period and the acceleration of progress in the world of life that accompanied the far-reaching geographical changes of the time. The next revolutionary event was the onset of widespread glaciation that began a new period and saw the effective beginnings of mankind.

In dealing with Palæolithic man, Dr. Hauser is thoroughly up-to-date, for he appears to have made use of all the evidence available up to the middle of 1926. He is particularly interested in the art and culture of early man, and by plotting the localities of significant discoveries he attempts to follow up the migrations of some of the recognised races. The book is beautifully printed and illustrated, and is a thoughtful contribution to the literature of its

subject.

#### Letters to the Editor.

#### Variation of Intensity Ratios of Optically Excited Spectrum Lines with the Intensity of the Exciting Light.

In a recent paper on the optical excitation of mercury vapour (*Phil. Mag*, Sept 1927) I directed attention to the fact that lines excited by two successive processes of absorption should increase with the square of the intensity of the exciting light, while lines resulting from a three-stage absorption should increase with the

cube of this intensity.

As an example of the last case, we may take the emission of the line  $\lambda 3650$  of mercury. The vapour of mercury at room temperature in a quartz tube, highly exhausted, is illuminated by the total radiation of a water-cooled quartz mercury arc. The absorption of the line  $\lambda 2537$  raises the electrons from 1S to  $2p_2$ , from which level they are raised to 1s by the absorption From 1s some fall to  $2p_1$ , a metastable level, with emission of \5461, and from here some are raised to the d level by the absorption of  $\lambda 3650$ , from which level they return to  $2p_1$  with emission of λ3650. If we move the arc away until the illumination of the vapour is reduced to one-half of its initial value, one would expect that the intensity of  $\lambda 2537$  would be reduced to one-half, of λ4358 and λ5461 to onequarter, and of \$\lambda 3650\$ to one-eighth of their initial values, for by reducing the illumination by one-half we have only half as many electrons raised from 1S to  $2p_2,$  owing to the reduced intensity of  $\lambda 2537.$  But  $\lambda 4358$  has been reduced by one-half as well, consequently there is but half as much light available for absorption by the reduced number of electrons in Lines resulting from a two-stage absorption process are thus reduced to one-quarter, and from a three-stage absorption to one-eighth of their initial values. Several observations bearing out this view were given, though a special investigation of the matter had not been made at the time.

Practically all of the light emitted by the tube results from two-stage or three-stage absorption. This accounts for something that has always surprised me, namely, the impossibility of obtaining a satisfactory amount of emission by forming an image of the lamp on the resonance tube by means of quartz lenses. I had attributed it the absorption of  $\lambda 2537$  by mercury vapour in the air, but the relations above

described amply account for it.

The phenomenon can be shown in a very spectacular manner by the very simple expedient of inserting a sheet of fine wire gauze, which is non-selective in reducing the intensities of the lines, first between the resonance tube and the eye, and then between the lamp and the resonance tube. We find that in the latter case the intensity of the emitted light is very much fainter than when the gauze is held between the eye and the tube. The gauze employed was of very fine copper wire, and transmitted about one-fifth of the light. When held between the eye and tube, the light was reduced to one-fifth, but when held between the lamp and the tube, the reduction was to one twenty-fifth; i.e. the light was almost invisible. A quantitative investigation of these relations is now in progress in collaboration with E. Gaviola.

R. W. Wood.

Johns Hopkins University, Oct. 16.

Biological Work in Russia, Siberia, and Turkestan.

My wife and I reached Leningrad early in July,

MY Wife and I reached Leningrad early in July, and left for England about the middle of September. In the interval we journeyed in Siberia so far as Lake Baikal, to Archan in the Buriat Republic, and to Tashkent in Usbekistan (Russian Turkestan). We visited the old town of Tashkent, where the women are veiled and the general aspect of things recalls the times of the Arabian Nights, until we notice the street cars, and entering a large mosque, find it converted into a cinema theatre, just then producing the American film 'Speed' We travelled far on the railways, more often in the 'hard' than the 'soft' cars, in one case for ten days, and talked with all sorts of fellow passengers, getting a good idea of the state of public opinion. We took long journeys in the springless country carts, seated on a small quantity of hay; and we slept in the houses of the peasants. Thus, although the time was short, we got a fairly good idea of the condition of affairs in U.S.S R. We were, however, on a strictly scientific mission, and what I have to say relates only to scientific work. The extent and variety of the biological investigations and institutions was greater than we could have supposed, and it seems worth

while to give some account of what we saw

I had heard of the University at Irkutsk, founded during the civil war, but was quite unprepared to see a great organisation, with numerous buildings and strong faculties. All this has come into being in less than ten years. At the head of the Biological Institute of the University is Prof. W. Schewiakoff, a zoologist of the first rank, well known for his magnificent studies of the Radiolaria, published in the series of Naples monographs. His wrife is a daughter of the famous zoologist Kovalevsky, remembered especially in connexion with Amphioxus. Prof. Schewiakoff has devoted himself to improving the facilities for teaching, and has developed a most beautiful series of anatomical preparations, with accompanying explanatory drawings. I have never seen anything more perfect of the kind, and all has been done with small funds and what we should consider extremely poor facilities. Thus one preparation, apparently in a museum jar, was really placed n a perfume bottle, with the top neatly cut off.
Prof. V. Dorogostaisky, whom I met later on the
shore of Lake Baikal, is a very keen zoologist, concerning himself with the domestication of fur-bearing animals, with the Baikal fishes, with the remarkable Amphipod Crustacea of Lake Baikal, and other matters. He showed me his exquisite series of watercolour drawings of Baikal Amphipods, many of them new. The paper will be published later by the Academy of Sciences at Leningrad. Prof. B. Swartschewsky, whom I met in Irkutsk, is also a zoologist concerning himself with the fauna of Baikal, and the author of important papers. I also met the botanist V. Jasnitsky, who is specially interested in algae, and has published on the plankton of Baikal and other matters. He has also a good knowledge of the local flowering plants, as I found when accompanying him in the field.

My wife and I were for some days guests at the biological station of the University of Irkutsk, situated on the shore of Lake Baikal. There we found a group of young people living happily together, investigating the fauna and flora, and doing excellent work. The beauty of the surroundings, and the endless fascination of Baikal, together with the good fellowship and enthusiasm in the station, produced an impression long to be remembered with pleasure. At Maritue, nearer the southern end of the lake, I visited the headquarters of the Baikal expeditions of

the Academy of Sciences, and was fortunate in finding there Prof. Nassonov, one of Russia's most distinguished zoologists. I used to correspond with him

about Coceidæ in the days before the War.

Later on we spent a week at Tashkent, in Usbekistan (Russian Turkestan). Here also I found a great University, developed since the War. There is also a very good laboratory of economic entomology, phytopathology, etc., which publishes excellent bulletins. One of its publications is an important illustrated work on the grasshoppers of Turkestan, by Uvarov, of the British Museum. The Tashkent Museum has been greatly developed in the last few years, and now contains very good collections illustrating the local fauna and flora, palæontology, works of art, etc. The director, Mr. Yankowsky, is a competent scientific man, specially interested in entomology. The Museum is called the Middle Asian Museum, and is officially connected with a society for the protection of ancient monuments and natural objects (in the language of the locality, Sred az com star-is). In this museum I was shown and allowed to study a series of the wonderful Jurassic fossil insects found near Galkino, in the neighbouring Cossack Republic. They have been largely collected and partly studied by Mrs. Besobrasoff, of the Faculty of Physics and Mathematics in the Central Asian University at Tashkent. She has described a new species of the extraordinary genus Kalligramma, while her sister has written a paper, shortly to appear, on the fossil fishes of the same deposit.

The entomologist at the University, Prof. N. N. Kuznetzov-Ugamsky, is especially interested in ants and sawflies, but has studied many other insects, and has written a paper describing a number of new bees of the genus Anthophora, a genus remarkably developed in Turkestan. Prof. Kuznetzov took mo on a collecting trip, and when I left, placed in my hands a large collection of Turkestan bees for study. Prof. N A. Keiser, zoologist at the University, is especially interested in hydrobiology, more particularly the Cladocera, but he and his students have collected in many groups. A party of 14 students, the majority women, went with him on an expedition to Lake Issik-Kul. He kindly handed me for study and report a series of land shells obtained on this expedition. Prof. Keiser gave me some account of the growth of his department. In 1918 they had only two rooms and 10 microscopes; now they have several rooms and 40 microscopes. About 500 students work in the department. The financial support is better each year. 1 was shown a collection of 500 large and

excellent charts made in the department.

In the Botanical Department I met Mr. Alexey Vvedensky, in charge of the herbarium. Within five years or so there has been built up a herbarium of about 20,000 sheets of Turkestan plants and 15,000 sheets of the flora of other regions or countries. Original work is being done and many new plants described. Numerous fascicles of "Herbarium Floræ Asiæ Mediæ" have been issued, together with pamphlets describing the plants when new, and giving full citations of literature when old. In the British Islands these are sent to Kew and Edinburgh; in the United States to the California Academy and the New York Botanical Garden.

During our stay both at Irkutsk and Tashkent, we were guests in the rooms of the respective branches of the Geological Committee. This organisation, centring in a very large building in Leningrad, is the Geological Survey of the U.S.S.R. It is purely scientific and non-political, doing work of the highest practical and theoretical importance. This year it has had about 200 geologists in the field. Our work

m U.S.S.R. was made possible by the hospitality and co-operation of the Geological Committee, and without this it is probable that we could have accomplished nothing. We were especially indebted to Mr Theodore F. Schwab, director of the branch at likutsk, who prepared matters for us before we arrived, so that we were given every advantage, and spared all friction and difficulty.

In Leningrad we of course visited the Academy of Sciences, and saw the famous zoological and geological museums—the mammoth taken from the ice of Siberia, the Baluchitherium skeleton of almost unbelievable size, the extraordinary great reptiles extracted from concretions of Permian age. The entomological collections are very fine and most excellently arranged; I spent some time examining the bees of the genus Andrena. I met several of the entomologists, but greatly to my regret missed Skorikov, the authority on Bombus, because the day he expected me was consumed in getting permission to leave the country. I was especially pleased to meet A. B. Martynov, the great authority on fossil msects and living Trichoptera. He showed me the amazing collections from the Jurassic of Turkestan, which open up a great new chapter on the lustory of insect development; and also the wonderful series of insects he found in the Permian concretions, a single block often containing numerous species, exquisitely preserved. I regard Martynov as one of the greatest masters of insect morphology of our times, and were I a young man I could think of nothing better than to study under his guidance.

We received great kindness at the hands of the veteran Dr. Karpinsky, the head of the Academy, and his daughter, Mme. Karpinsky. The latter is a sort of guardian angel to foreign scientific people visiting Leningrad, much as Mrs. Britton is to

botanists visiting New York.

The Lenngrad Botanical Garden, occupying 15 acres, is a great centre of botanical work, and its library is said to be second only to that of Kew. The grounds are now being reorganised by a force of 300 men, but we saw very good exhibits of the flowering plants of different parts of U.S.S.R. The hothouses are full of interesting things. We were taken over the gardens by Prof. Komaroff, well known for his important studies of the flora of Eastern Siberia and the Mongolian Region.

There is a small botanic garden at Tashkent, the principal exhibit being a fine *Victoria regia* water-lily in a tank in the open. Many of the trees (as honey-locust, box-elder, and Robmia) planted along the walks are of American origin. Near the gate is a fine specimen of the Asiatic *Juglans fallax* Dode.

#### The Maxwell Effect in Liquids.

CLERK MAXWELL many years ago surmised that viscous liquids in a state of flow should exhibit birefringence, and devised methods of observing the phenomenon. Vorlander and Walter (Zeits. Phys. Chem., 118, 1; 1925) have recently investigated no fewer than 172 liquids of known chemical composition by Maxwell's method, and their work has demonstrated conclusively that a great many pure liquids which cannot by any stretch of language be classed as colloids, exhibit birefringence when subjected to viscous flow. The Maxwell effect, as it may be called, is thus a characteristic property of pure liquids just as much as the power of exhibiting birefringence in strong electrostatic or magnetic fields. We wish

bers.

briefly in this note to indicate a molecular theory of the Maxwell effect we have worked out which has proved itself very successful in explaining the observed phenomena.

It is easily seen that the stresses in flowing liquid can be considered as equivalent to a set of tensions and a set of pressures acting perpendicularly to each other, and at angles of 45° to the plane of sliding. When the liquid consists of molecules which are highly asymmetric in shape, there would be a tendency for the molecules to orientate under the influence of this system of stresses in such manner that the longest dimension of a molecule tends to lie along the axis of tensions and the shortest one along that of pressures; because such orientation would evidently result in the fluid, regarded as a densely packed assemblage of molecules, expanding along the direction of tensions and contracting along the direction of pressures, thus allowing the system of stresses to do work. By considering the work done during such deformation by the acting stresses as equivalent to the change of energy of the molecules resulting from orientation under a system of couples acting upon them, we can determine the latter in terms of the viscous forces and the asymmetry of shape of the molecules; it being remembered that the orientation is opposed by the thermal agitation of the fluid and that the resulting equilibrium is to be determined statistically in accordance with the Boltzmann principle.

The birefringence of the fluid resulting from the orientation of the molecules under the viscous stresses and their known optical anisotropy, is then readily worked out on lines analogous to those used by Langevin in his theory of electric and magnetic double refraction. The final expression obtained in this way for the difference between the refractive indices  $n_t$  and  $n_p$  for the vibrations along the axes of tensions and pressures respectively, is:

$$n_z - n_p = \frac{(n^2 - 1)(n^2 + 2)}{5n\nu kT}$$

$$\begin{split} & n_{t} - n_{p} = \frac{(n^{2} - 1)(n^{2} + 2)}{5n\nu kT} \\ & \cdot \frac{(a_{1} - a_{2})(b_{1} - b_{2}) + (a_{2} - a_{3})(b_{2} - b_{3}) + (a_{3} - a_{1})(b_{3} - b_{1})}{(a_{1} + a_{2} + a_{3})(b_{1} + b_{2} + b_{3})} \cdot \eta_{c}^{v}, \end{split}$$

where n is the mean refractive index of the fluid,  $\nu$  is the number of molecules per unit volume, k is the Boltzmann constant, T is the absolute temperature,  $a_1$ ,  $a_2$ ,  $a_3$  are the linear dimensions of the molecule along the three principal axes,  $b_1$ ,  $b_2$ ,  $b_3$  are the optical moments induced in the molecule along these axes by unit field acting on it successively along the same three directions,  $\eta$  is the coefficient of viscosity and v/c is the velocity gradient

The birefringence calculated from our formula, utilising the optical anisotropy ascertained from observations on light scattering and the geometrical dimensions derived from X-ray data, comes out in excellent agreement with the determinations of Vorlander and Walter.

The extension of the theory to the case of colloidal solutions and gels is at present engaging our attention.

#### The Excitation of Spectra by High Frequency Oscillations.

THE letter in Nature of Oct. 8, p. 510, from Prof. R. W. Wood and Mr. Loomis directs attention to the possibility of developing spectra by means of high frequency oscillations Work on these lines has been proceeding in this department for some time, and the results obtained with mercury as a 'trial horse' are

A short coil of copper tubing was wound round a horizontal hard glass tube through which a stream of mercury vapour was caused to flow. The coil was connected in parallel with a condenser, and oscillations were maintained in this circuit by means of a highpower three-electrode valve. The frequency of these oscillations was of the order of 106 cycles per second, the voltage applied to the circuit could be varied from 2000 to 10,000 volts, and the power input increased up to 3.5 kilowatts. The pressure inside the glass tube was adjustable by the admission of air, and the spectrum produced when the coil was activated was examined end-on by means of a quartz spectro-

Before a glow was visible, the resonance line λ2536 7 was photographed with a long exposure. An increase of the voltage applied to the circuit caused the appearance of a greenish glow, which was found to be due to the lines of the s and d triplet series in addition to this line; prolonging the exposure only resulted in more members of these series being recorded. A further increase in the voltage caused the colour of the glow to change to that of the ordinary mercury arc, the photographs now showing the resonance line, the s and d triplets, the lines of the S and D singlet series, and some combination lines. Only those combination lines were present, however, which involved the arrival and departure levels of the series lines present. When the voltage was still further

increased, more members of the triplet and singlet series were developed, together with additional

combination lines connected with these new mem-

Simultaneously excited, however, were also thirteen lines, which have not yet been allocated to any series or combination, though these have all been identified as being present in the ordinary mercury arc. Their wave-lengths were 3984 1, 3860 4, 3820 6, 3790 4, 3751 8, 3561 5, 3543.7, 3390 5, 3351 5, 2820 0, 2686.7, 2660 1, and 2540 4. They were all of very feeble intensity except the first, which was as strong as an early member of the triplet series. A step by step reduction of the pressure from 1 cm. to that of the vapour alone, keeping the voltage constant, produced the same effects as increasing the voltage when the pressure was constant. An increase in the temperature of the vapour also facilitated the development of the lines. The line λ3984·1 was abnormally affected by pressure; increasing the pressure caused it to fade much more rapidly than the other lines.

It had been anticipated that enhanced lines due to atoms in various stages of ionisation might have been obtained, especially near the circumference of the tube, but these have not yet been observed; further endeavours to obtain them will be made. is remarkable that although several of the lines of the p series are present in the ordinary arc with an intensity as great as that of some of the higher members of the s and d series, yet they have not been observed as being excited by this method, even when the exposure has been prolonged up to five hours. It is possible that they require higher voltages for their excitation than have been available so far.

It is apparent that this method of developing spectra is full of promise, and its extension to other elements than mercury, the spectra of which have not yet been analysed so completely, is proceeding. J. R. CLARKE.

#### The Mechanism of Formation of the Latent Photographic Image.

It is with great interest that I see in Nature of Sept. 24, p. 441, Dr Toy's letter with regard to the part played by the photo-electric conduction effect in the formation of the latent image on silver halide

At the Detroit meeting of the American Chemical Society on Sept. 10 last I read a paper in which I presented a tentative picture of a mechanism for the formation of the latent image based on the known facts of silver halide and silver sulphide An earlier paper on the same subject will appear in the November number of the Journal of the Franklin Institute.

E. P Wightman and R F. Quirk, at the American Chemical Society meeting in Sept 1926, stated in their second paper on "Intensification of the Latent Image on Photographic Plates and Films," that they believed that the sensitivity spots on silver halide grains contain some silver in addition to the silver sulplinde. W Clark independently, in his experiments on the action of oxidisers on the sensitivity and latent mage, supports this view of Wightman and Quirk. He concludes: "It appears, then, that the results obtained could be explained on the view that silver sulfide is present in the sensitivity substance provided it is postulated that there is also present something—say, silver—which is attackable by oxidisers of potentials too low to attack silver sulfide."

Assuming that the explanations of Wightman, Quirk, and Clark are correct, we have in our high sensitivity photographic materials to deal with the

silver | silver halide | silver sulphide in which silver and silver sulphide are in contact with each other. This system represents a photo-electric cell of the Becquerel type, in which silver is the cathode, silver sulphide is the anode, and silver halide is the solid electrolyte

In light, the potential difference between the electrodes increases, the conductivity of the silver halide increases (i.e. photo-conductivity), and an electric current flows around in this closed system. The result will be an electrolysis of the silver halide, the cations moving towards the cathode (concentration speck theory; coagulation theory of the latent image), the anions losing their charge and staying in the crystal substance (Tubandt).

The photo-electric action according to the old

theory (Fajans) was

 $[Ag^+, halogen^-] = Ag + halogen.$ 

The halogen ion loses an electron, which moves towards the silver ion, thus discharging the silver cation. According to the above proposed theory, the electron from the halogen anion liberated by the light absorption moves towards the silver sulphide anode, then goes to the cathode; at the same time, the

Ag | Ag<sub>2</sub>S<sup>+</sup> [Ag+ Halogen-]

silver cation moves towards the cathode and is there discharged by the electron from the halogen anion. If the silver speck has grown to a certain size, developability is introduced.

This picture of the formation of the latent image also takes into account the failure of the reciprocity

law and the intermittency effect.

One of the difficulties in the photo-electric conduction theory of the latent image has been the wavelength effect, which has now been removed by the valuable work of Dr. Toy. A. P. F. TRIVELLI.

#### Some Further Spectral Lines of Trebly-ionised Germanium.

Carroll (Phil. Trans. Roy. Soc., vol. 225, p. 357) has identified the first members of each of the first principal, sharp, diffuse, and fundamental series of trebly-ionised germanium (Ge IV), which in Hund's notation may be represented by  $4S_1 - 4P_1$ ,  $2 \cdot 4P_1$ ,  $2 \cdot 5S_1$ ,  $4P_1$ ,  $2 \cdot 4P_2$ , 3 and  $4D_2$ ,  $3 \cdot 4F_3$ , 1 respectively. All these lines lie in the Schumann region. Using a condensed spark between metallic electrodes mvacuo, the near ultra-violet region has been examined for further spectral lines of Ge IV by means of a concave grating of radius 2 metres arranged on a Rowland mounting.

The first members of the second principal series  $5S_1$  -  $5P_1$ , 2 were easily found at  $\lambda\lambda 3554$  and 3676. A triplet resulting from combinations between  $4D_{2,\,3}$ and  $5P_1$ , 2 has also been identified. Taking Carroll's value 178094 for the wave-number of  $4D_2$ , the  $4D_2$ ,  $_3-5P_1$ , 2 triplet yields for  $5P_1$  and  $5P_2$  the wave-numbers 142242 and 141305 respectively. These terms combining with  $4S_1$  would give a doublet, namely, the second member of the first principal series, of wave-number 227396 and 226459. This doublet has been found by Dr. R J. Lang, to whom I am indebted for the measures of these lines and permission to include them in the table below. discrepancy between the estimated and measured wave-numbers of these lines is due to a lack of adequately accurate standards in the  $\lambda400$  region.

The measures are given in the following table.

Intensity	λI.A. air.	ν	$d_{\nu}$ .	Term Combination
8 9	3676·61 3554·14	27191·3 28128 2	936-9	$ \begin{array}{c c} 5S_1 - 5P_1 \\ 5S_1 - 5P_2 \end{array} $
5 5 1	2788 41 2736 09 2717 41	25852·2— 36537·7— 36788·9	$\begin{bmatrix} \cdots 936.7 \\ \cdot \cdot \cdot 251.2 \end{bmatrix}$	$\begin{vmatrix} 4D_2 - 5P_1 \\ 4D_3 - 5P_2 \\ 4D_2 - 5P_2 \end{vmatrix}$
1 1	441·95 440·11	226270 227216	} 916 {	$\begin{vmatrix} 4S_1 - 5P_1 \\ 4S_1 - 5P_2 \end{vmatrix}$

# The 'Green Flash' at Sunrise.

WATCHING the sunrise this morning across the Nile valley, under conditions of very good visibility and no local wind, using Goerz ×8 binoculars, I saw what is, to the best of my knowledge, a novel form of the 'green flash.'

From the top floor of Mena House Hotel the sunrise was behind Gebel Tura, with its skyline at about 300 metres elevation, and some 25 kilometres away. The dawn was clear, a light white mist lying low on the valley floor; the sky was cumamon colour, changing to amber as the sun rose; the desert hills appeared deep blue to the naked eye, and brownish purple through the field-glasses.

The form of the actual flash was totally unexpected; it preceded the emergence of the limb of the sun itself by perhaps as much as two seconds, and I can only describe it as resembling a shallow and turbulent river of apple-green water hanging ready to break over the hill crest. But this river flowed with a surface which seemed to follow the minor prominences of the skyline, instead of first appearing between them; it appeared suddenly, not seeming to widen much after its first apparition, the greatest width attained being perhaps one-third of the diameter of the sun's disc. At the emergence of the orange-gold disc in the centre of this pale-green band, the two colours seemed momentarily to co-exist, this was probably persistence of vision, but indicates that there was no eye-fatigue

The intensity of the green was never the vivid emerald of sunset which I have twice seen, once in the Mediterranean and once in Upper Egypt; it was the paler colour, which is less uncommon. Probably the actual intensity of the colour is a matter of luck. The fact of the flash appearing at sunrise seems finally to exclude any physiological cause, and agrees with the explanation of refraction through air layers of different temperatures. The apparent turbulence might well be real turbulence of the air, induced as the desert starts to be warmed by the sun's first rays W. Lawrence Balls.

Cairo, Oct. 26.

# Influence of X-rays upon Time-lags of the Faraday Effect and upon Optical Rotation in Liquids.

Differences in the time-lags of the Faraday effect behind the magnetic field in various liquids have been measured by Beams and Allison (*Phys Rev.*, 29, 161; 1927). Certain considerations have led me to suspect that these time-lag differences might be affected, and even reduced to zero, by the action of X-rays on the liquid. A number of experimental tests very recently carried out demonstrate that the X-rays have such a property. It was found in every case that the time-lag differences of the Faraday effect between any pair of the liquids vanished so long as the liquids were exposed to the X-rays, and that the lags were restored with the screening off of the X-rays. The liquids thus far used are carbon disulphide, carbon tetrachloride, ethyl alcohol, xylene, and chloroform.

The method also affords a means of measuring the absolute time-lags of the Faraday effect, giving values for the various liquids which are consistent with the previously measured time-lag differences.

This work having shown an influence of X-rays upon the lag of the Faraday effect, it was decided to find out whether these rays could produce an effect in rotating the plane of polarisation of light in these same liquids. A preliminary series of tests shows that a beam of X-rays traversing the liquids does impart to them the power of rotating the plane of polarisation, though it is small.

These investigations are being continued, and it is hoped that a detailed report of them will be published in the near future FRED ALLISON.

Alabama Polytechnic Institute, Auburn, Alabama,

Oct. 11.

# Synthesis of Rubiadin.

My attention has been directed to a paper in the August (1927) issue of the Journal of the American Chemical Society (p. 2043), in which Stauder and Adams have shown that rubiadin is not 1,3-dihydroxy-4-methylanthraquinone. It is of interest to record that we came to the same conclusion by condensing cresorsellimic acid with benzoic acid in presence of sulphuric acid.

1,3-Dihydroxy-4-methylanthraquinone melts at 265°-266° (not 251°, as found by Stauder and Adams) and the diacetyl derivative melts at 181°-182°. The deacetylation product melts at 265°-266°. We have also succeeded in synthesising rubiadin itself by condensing dihydroxyparatoluic acid with benzoic

acid (Schunck and Marchlewski's original method). Papers dealing with this work have already been communicated to the *Journal of the Indian Chemical Society*.

It is interesting to note that with the elimination of rubiadin from the list of  $\alpha$ -methylanthraquinone derivatives there is not a single natural product (of proved constitution) left in that list. Substances like emodin, chrysarobin, chrysophanic acid, etc., which have at one time or another been regarded as  $\alpha$ -methylanthraquinone derivatives, have all been since proved to be  $\beta$ -methylanthraquinone derivatives. It is curious to note in this connexion that while 3-methylanthracene occurs in coal tar,  $\alpha$ -methylanthracene is a purely artificial product.

P. C. MITTER.

University College of Science, Calcutta, Sept. 29.

#### Orientation of the 'Devil's Arrows,' Boroughbridge, Yorks.

At the recent meeting of the British Association at Leeds, Excursions Handbook Q was issued for members taking part in excursion No. 18 to Aldborough and the 'Devil's Arrows.' On pages 16 and 17 of this handbook there are remarks on this monument, and a plan of the positions of the three megaliths of which it is formed, for which we are responsible.

It is now found that the measurements and azimuths on which the plan was plotted are inaccurate, and that the positions of the three stones do not, as there shown, fall on the arc of a circle. The theory derived from this supposition, namely, that the three stones originally formed part either of a great stone circle or were the remains of the peristalith of a tumulus, must therefore be abandoned.

The 25-inch Ordnance Survey map of the site shows that the three stones are actually almost in alinement. From the northern monolith the azimuths of the other two he between 151° 00′ and 152° 30′, approximately, while the distance from the northern stone to the middle one is 200 feet, and from the northern to the southernmost is 570 feet (also approximately)

BOYLE T. SOMERVILLE.

#### An Active Form of Oxygen.

HERBERT E. WROOT.

An active form of oxygen, presumably monatomic, has been produced by passing oxygen gas saturated with water vapour through a discharge tube. The oxygen was generated electrolytically and subjected to a discharge of about 1000 volts at a gas pressure of  $0.4\,$  mm. of mercury. The gas was removed from the discharge tube through a side arm, and its density measured by passing it through a small hole which was located at a distance of 25 cm. from the discharge tube. Pressure measurements at the small hole indicated a decrease in the density of the gas corresponding to about 8 per cent. monatomic oxygen. A platinum calorimeter mounted over the hole showed a decided rise in temperature during the passage of the discharge. These effects were continuous throughout one 3-hour experiment. This work is being continued with the object of determining the most favourable conditions of studying the chemical properties of this gas. It is also hoped that a measurement of the heat of association may soon be completed.

# Research in the Textile Industry.1

THE eleventh annual report of the Committee of the Privy Council for Scientific and Industrial Research gives a comprehensive survey of the state of research in the various branches of industry, and of developments in industrial research since that Committee was established The record is both impressive and instructive. In its survey of the great productive industries it points out that "the textile industries, though the largest manufacturing industries of the country, are by contrast with other industries . . far more dependent on their own efforts for the prosecution of research and for the specialised training of their technical staff. While engineering, metallurgy, and industrial chemistry are considered suitable subjects for university research, there are no university organisations for research into textile problems except at Leeds and Manchester. There is no obvious reason for this, except that the subject from a scientific point of view is more difficult.'

At the recent meeting of the British Association, considerable attention was for the first time given to this subject of research in the textile industries. Several papers were contributed upon textile problems and the difficulties of research workers in the textile industry were emphasised. Attention was directed to the considerable volume of work which is being conducted by the Textile Institute and by similar professional bodies which are concerned with allied branches of the industry, and to the fact that although, as the Report of the Committee of the Privy Council states, the only university organisations for textile research are at Leeds and Manchester, a large volume of first-rate work is being and has already been done by the Cotton, Silk, Linen, and Woollen and Worsted Research Associations, as well as by academic and quasiacademic bodies such as the College of Technology at Belfast, the University College at Nottingham, the Imperial Institute, the Manchester Chamber of Commerce's Testing House, and the Conditioning House and Technical College at Bradford.

The British Association would have done a useful work if it had merely succeeded in focussing the attention of the academic and scientific world upon this matter. In directing attention to the fact that the fundamentals upon which the researcher in textiles has to work are just as indefinite, and at least as variable, as the fundamentals in any branch of science and technology with which the universities have been in the habit of intimately concerning themselves, it has, however, done much more. If, therefore, the meeting has succeeded in ensuring that textile teaching and research shall and ought properly to form an integral part of university and higher technological training, and no longer remain an almost despised Cinderella of subjects, it will have rendered a signal service to the industry and probably no less a service to the academic world.

No. 3029, Vol. 120]

<sup>1</sup> The British Research Association for the Woollen and Worsted Industries An Outline of its Activities. Leeds: Torringdon, Headingley. 1927.

Naturally the British Research Association for the Woollen and Worsted Industries, and its work, received considerable attention from the members of the British Association. This Research Association owes its inception and development partly to the Department of Scientific and Industrial Research, from which body it has received, in common with other research associations, very considerable monetary grants, and partly to the mitiative and enterprise of certain West Riding industrialists It has been guided in its development by a distinguished Council, over which Sir James Hinchliffe, a noted leader of advanced thought in the West Riding, has presided since its formation

The Research Association has, in common with the other bodies which have concerned themselves with textile research, had to consider problems in the two categories into which all research in connexion with the industry may be conveniently divided. It has considered the industrial or practical problems of the industry, and also the scientific principles underlying all the industrial operations. In order that the necessary experimental work might be carried out, it has established physical, chemical, and biological laboratories as well as machinery rooms in which manufacturing processes may be studied from an experimental point of view. The progress which has been made has necessarily been slow, though probably no less rapid than is usual with the development of theory in any other branch of science and technology. Its work, however, seems very clearly to have demonstrated two points; it has shown, first of all, that although the textile industry has been developed by what are sometimes described as unscientific men, yet their achievements have reached a remarkable standard of accuracy, and secondly, that spectacular development and invention is, very possibly, unlikely to take place in the future. Moreover, it has emphasised the vital fact that the gradual introduction of a special technologist capable of interpreting the thought and work of the investigators in pure and applied science is indispensable if the gulf which has so far existed between the industry and the field of genuine research is to be successfully bridged.

The nature of the fundamental problem which presents itself to the textile researcher may be appreciated by the consideration of the raw material of the industry, namely, the wool fibre. Examples of fibres (under the same magnification) of (a) Lincoln, (b) Merino, and (c) Crossbred wools are given in Fig. 1. These photomicrographs illustrate very clearly the variation in diameter and physical structure of three typical wools. It is evident that a complete knowledge of the wool fibre is essential and must ultimately become available, and that this knowledge will involve full information of the structure and physical and chemical properties of the fibre. Such information does not at present exist. In the industry the value of raw wool is, from a monetary as well as from a manufacturing

point of view, at present judged by what is called its 'quality' Quality is a term or number used to connote the probable spinning value of the wools (termed combing wools) employed in the worsted industry. Whilst it is true that experienced members of the worsted industry are able to gauge with remarkable accuracy the quality number or the counts to which a particular wool will spin, yet for this fundamental characteristic the industry has at present no definite measure. The quality of a fibre may, for example, depend on diameter, length, and elasticity, and each of these provides, in itself, a subject for research Important biological and physical problems must be considered in connexion with the length of the staple, while the elasticity involves a knowledge of the physical, and probably of the chemical, structure of the fibre

These matters are fundamental subjects of importance upon which the Woollen and Worsted

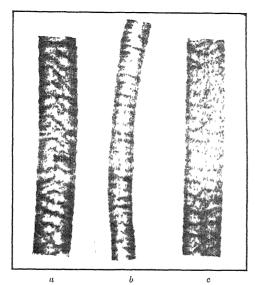

Fig. 1—Wool fibres.

a, Lincoln wool fibre, b, merino wool fibre; c, crossbred wool fibre

Research Association, as well as several other workers in textile technology, are now engaged. In "An Outline of its Activities," a recent publication of the Woollen and Worsted Research Association, the present position has been summarised. This report states, inter alia, that "at present there is an entire lack of definite knowledge on both points [the determination of the precise characteristics of and the best means of production of the raw material] regarding this raw material. The primary factor is to investigate those points regarding quality which may be expected to have a direct bearing on the economic value of the fleece."

Some of the chemical problems which have engaged the attention of the textile researcher are of special interest, indicating as they do the extent of the field for systematic research. The method of elimination of grease from raw wool by scouring with soap and alkali is being investigated. The soaps used may not, after scouring, be completely eliminated from the wool, and it appears that unless

the soaps are made from suitable fatty acids, other products are produced after scouring takes place, and these products materially affect subsequent processes, such as dyeing and finishing, to which the wool, in one form or another, is subjected. A preliminary examination appears to show that the absorption of alkali by wool may increase the susceptibility of the resulting cloth to bacterial action and may cause the dyeing affinity to vary from point to point of the cloth. The cause of this variation in distribution of the alkali after scouring is not merely mechanical but is undoubtedly related to alkali migration and to chemical action

Probably one of the most important aspects of the chemical work of the Research Association, a reference to which is made in the recent publication of the Association, is an investigation which it is conducting jointly with the Society of Dyers and Colourists. This investigation, which is being directed by a joint committee, will, it is understood, include initially fastness tests for sunlight, washing, and perspiration. The fastness tables which are already in existence do not give a definite fastness test to dyed materials, because the tests have so far been applied to single dyestuffs only. In practice, dveing by single dyestuffs is not usual The work which is now in process should thus enable the preparation of a complete standard for dved or coloured materials

One of the most interesting, though at the same time incomplete, investigations which has been made is the physical examination of the wool fibre The report of the Research Association states that "wool is an amphoteric colloid which in regard to physical and chemical relations presents the well-known colloidal characteristics." Dr. Shorter, in the Transactions of the Faraday Society, describes his attempts to develop a complete colloidal theory of the elasticity of the wool fibre In his theory he attributes "to the fibre the characteristics of a two-phase system consisting of an elastic frame-work (the elastic phase), the interstices of which contain a viscous medium (the viscous phase)" The elaboration and extension of such physical work must ultimately yield results of fundamental importance in so far as the primary formation of the fibre is concerned

Other investigations, though probably of no less fundamental significance but of immediate practical importance, are being made into the thermal conductivity of wool, its electrification and electrical conductivity, its elasticity, and especially into the effect of moisture upon it. The action of water upon wool is of immense practical importance, as it has a well-defined effect upon the combing, spinning, and manufacturing properties of the fibre, and depends to a very large extent upon the degree of moisture and the conditions under which the moisture reacts with the wool. It is, of course, well known that one of the reasons for the prosperity of the textile industry in Yorkshire and Lancashire is the dampness of the climate in those areas. This condition formerly made possible operations in those areas which could not be carried out as efficiently elsewhere The advent of systems of artificial humidification have, however, neutralised to some extent the natural advantages of the climates of those localities, and the work to which reference has already been made indicates that a complete knowledge of the mechanism of these actions is now within measurable distance.

The development of textile research would appear to deserve not only the attention which the British Association has properly given to it, but also the best which can be afforded by our academic and industrial bodies. Research is not, and should not be, the responsibility of one particular body. The research associations can do a great deal. The industries and the large academic bodies have also

an equally important duty to perform. The cooperation and sympathetic efforts of all these bodies should, however, ensure that textile research shall, under the favourable conditions which now exist, enter upon one of the most important stages in its development. Whitehead, in the preface to his "Principles of Natural Knowledge," points out that his inquiry "raises more difficulties than those which it professes to settle. This is inevitable in any philosophical work. . . . All that any one can hope to do is to settle the right sort of difficulties and to raise the right sort of ulterior questions, and thus accomplish one short step further into the unfathomable mystery." So it is with our textile researches

# The Germplasm and its Architecture.1

By Dr. F. A. E. CREW.

THE neo-Mendelian theory is like its parents a particulate theory, implying that the germplasm of organisms is not an indivisible whole but an organisation of units or factors which can be dissociated and recombined in various ways, just in the same manner as on the atomic theory a chemical compound is not a thing indivisible but an organisation of units which can be dissociated and recombined in other ways. But it differs from the theories that have gone before in that it is not purest speculation, incapable of confirmatory test; it is not merely an ad hoc explanation. It is not a preformatist doctrine, for no one ever seriously held that a factor was in any way a miniature replica or even was representative of a single character. The term unit character itself has been dropped, for it was misleading in view of the manifest fact that characters can never be units. The attitude of the geneticist in regard to the architecture of the germplasm is similar to that of the chemist in regard to the atomic constitution of matter. It is held that the hereditary constitution of an individual is not only composed of units in particular proportions and arrangement, but that its effects are determined by these proportions and by this arrangement just as much as by the particular nature of the units themselves. A character is the resultant of a large number of agencies of the internal environment of the zygote interacting with a large number of agencies of the external environment.

Weismann, in constructing his edifice of theory, with its purely hypothetical determinants, biophors, and ids, at least did one thing that must make his name immortal; he attached his speculations to something tangible by locating his units in the then newly investigated chromosomes. In this guess he enshrined the truth, for *Drosophila melanogaster*, in the hands of Morgan, Bridges, Sturtevant, Muller, and their colleagues, has provided definite and final proof that the chromosomes are indeed the germplasm, that upon each chromosome is borne a certain definite association of the hereditary factors or genes, and that each gene has its own particular place upon a particular chromosome. It has been

<sup>1</sup> Continued from p. 698.

possible in the case of Drosophila to construct a map of the chromosomes showing the relative position of all the genes so far discovered, and this map, like a railway time-table, giving the sequence of the places and the distance between them, in the hands of the breeder of this animal endows him with the powers of the synthetic chemist in the manipulation of his own material.

As yet, there exists but little exact knowledge of the chemical nature of chromatin: it is known, however, that it is intimately related to the activities of the cell as a whole, that it has a definite architecture and disposition within the nucleus; that during cell division it becomes condensed and homogeneous and then displays most clearly its organisation into units, the chromosomes. It is established that the number, size, form, and behaviour of the chromosomes are constant in a species and are characteristic of that species. It is known that even when the chromatin is thus condensed in the form of chromosomes, it still retains its organic contact with the non-chromatic part of the cell of which it is but a part, though an essential part: it is established that no development is possible at all in the absence of at least one haploid set of chromosomes. It has been amply demonstrated that the only identifiable cell organ which can satisfy the demands made upon the germplasm by the results of countless experiments are the chromosomes, and that in the behaviour of these are realised the precise conditions of hereditary transmission as recorded by observation.

The exact parallelism between the distribution of the chromosomes and the distribution of the hereditary characters affords an explanation of the ratios obtained in experiments involving freely assorting characters, if it is assumed that within the chromosomes are resident the genes, for the gene within the chromosome must necessarily go whither the chromosome passes. It is established that the chromosomes in the immature gamete and in the body cells generally are present in pairs, and that of each pair one member has been received from each parental organism. It has been demonstrated that in the ripe gamete only one member of each pair of

homologous chromosomes is present, and moreover, that the sorting of the chromosomes during the maturation of the gamete is at random, the distribution of one member of one pair being in no way influenced by that of either member of any other pair. It is not difficult, therefore, to explain the results of an experiment involving more than one pair of factors and giving free assortment and recombination, for all that must be postulated is that the different factor pairs are resident in different chromosome pairs.

The facts of linkage can be interpreted by postulating that the factors for linked characters are resident in one and the same chromosome, and that for this reason they must remain together in inheritance so long as the chromosome concerned retains The facts of crossing-over can be its integrity explained by postulating that the cause of this is an interchange of material between the members of a pair of homologous chromosomes, these chromosomes being dissimilar in their genetic constitution. It is frankly admitted that in this matter of crossingover genetics has outrun cytology, just as at one time cytology had outpaced genetics in regard to the mechanism of sex-determination, but the fact of crossing-over must not be confused with the validity or otherwise of the suggestion put forward to explain it. It is the case that during the maturation division in gametogenesis the segregation of homologous chromosomes is complicated by the fact that the members of each pair, prior to their separation, become most intimately intertwined. This apparently single, but really double, chromosome then splits longitudinally. This conjugation of homologous chromosomes provides the opportunity for crossing-over. It cannot be shown to have occurred, but if during this conjugation the two chromosomes stick, fracture, and rejoin before separation, then interchange of chromatin will have occurred. It is not without significance that conjugation occurs when the chromosomes are drawn out to their greatest attenuation, so that the homologous chromomeres derived from the two parents achieve the maximum degree of association in a linear series.

It is seen that the equivalent chromosome contributions of the two parents and their random assortment in maturation and chance recombination in fertilisation, together with the possibility of an inner reorganisation of each chromosome through its most intimate association with another of identical structure but different content, provide an infinite range of new combinations of character which can be tested out by environmental agencies. The chromosome mechanism can supply the variations upon which the forces of selection can operate. It becomes apparent also that this conjugation of chromosomes in synapsis excludes the possibility of fruitful crosses between species widely different in chromosome constitution.

If the conjugation of homologous chromosomes is accepted as evidence in support of the conception of crossing-over, and if the genes are strung like beads upon a string, each particular gene having its own particular locus upon a particular chromosome,

then it follows that the percentage of crossing-over between any two loci can be regarded as an indication of the distance between them. If the members of a pair of homologous chromosomes during their conjugation are as likely to fracture and reunite at one point as at any other point along their length, it follows that the farther apart any two genes lie in the chromosome, the greater is the chance of crossing-over occurring; and, conversely, the nearer together the genes lie, the smaller is the chance of crossing-over occurring If this is so, then it is possible to construct a map of the chromosomes, showing the relative positions of the different genes resident in each. If A, B, and C form a linear series, and if B has between A and C, then the crossing-over percentage occurring between A and C should equal the sum of the crossing-over between A and B,  $\hat{B}$  and C.

The conception of the localisation of the genes in linear alinement is due to the peculiar differences between the crossing-over between genes of the same character linkage group. The relation of three or more points to each other is a relation of linear order and cannot be represented in space in any other manner than by a series of points arranged in a line. Linearity is the expression of a system in which there is a fixed succession of elements. The distance between any two elements is constant but is variable throughout the series. In the case of the more simply organised forms of life it is possible to conceive the germplasm having the form of a congeries of chromatin units, the members of which can exist separately within the nucleus and become associated by chance. In the more complex forms, however, the precision exhibited in the inheritance of a most complicated characterisation demands a very precise and more complex hereditary mechanism, such as is supplied by the chromosomes in their constitution and behaviour.

The Columbia school has practically completed the essentials of the static theory of heredity concerning the existence and distribution of genetic units initiated by Mendel. The germplasm has been identified and its architecture defined. The chromatin material of the nucleus of the cell is the germplasm and the hereditary units are the genes. A gene is a particular state of organisation of the chromatin at a particular point along the length of a particular chromosome. It is a particular area or locus of the chromosome in a particular state. One particular condition of this chromatin can be replaced by others and with each change another gene appears.

The Columbia school has, however, done more: it has initiated a dynamic theory concerning the relation of these genetic units to development. Bridges, out of his magnificent work on balanced intersexuality in Drosophila, was able to lay the foundations of the fundamental theory of genic balance, according to which the effect of a gene depends not only upon environmental conditions but also and particularly upon the other genes with which it is associated in the hereditary constitution of the individual. Bridges has proven up to the hilt that the sex-chromosomes exert their effects

not per se but only when in a certain relation with other chromosomes. Further, it has been shown that the subtraction or addition of whole chromosomes or of whole sets of chromosomes, as in haploid or polyploid individuals, is associated with constant and definite variations in characterisation. This observation, first made by Gates, has been extended, for example, by Bridges to Drosophila, by Wettstein to mosses, and by Blakeslee to Datura

It is an obvious fact that the extent of our knowledge of the genetics of a particular form is determined by the frequency of mutation in that form. So much is known of Drosophila, because, amongst other things, observed mutation in this form is relatively common. The gene is stable and so far has resisted most attempts to modify it experimentally. It will be recognised that if the usual genetical methods of investigation are to be used, then in the case of an animal or plant of economic importance in which mutation is rare, there can be no rapid increase in our knowledge of the genetics of this form until it has become possible to provoke mutation at will. It has been reported repeatedly that germinal changes, presumably mutational, had been induced by X-rays, radium, alcohol, lead, antibodies, and so forth, but the interpretation of the data thus secured has been highly disputatious. It is known that X-rays can and do affect the distributive mechanism of the chromosomes and the phenomenon of linkage, and it is now reported by Muller that radiations of short wave-length can produce gene mutations in a high proportion of germ cells so treated. Mutations thus produced are stable in their inheritance and behave in a manner typical of Mendelian chromosomal mutant genes found in organisms generally. Such treatment produces an increase of about 15,000 per cent. in the mutation rate of the stock. Many of the mutations invoked are those which have previously appeared in Drosophila; many, on the other hand, are mutations in loci, in which mutation apparently has never been observed

Through the use of appropriate doses of X-rays |

also it has been found to be possible to provoke a high proportion of rearrangements in the linear order of the genes associated with fragmentations and translocation of portions of a chromosome. Here, lying now m our hands, is the very tool wherewith to explore the hereditary constitution of animals and plants of interest and of economic importance No longer must we wait for mutations to occur · no longer need we squabble amongst ourselves concerning the rôle of external agencies in the provocation of mutation, for it is demonstrated that it is possible in our chosen experimental stocks to manufacture series of artificial strains for use in the study of genetic and phænogenetic phenomena It may soon be possible to produce to order sufficient mutations to furnish adequate chromosome maps, and thereby to give to the breeder of domesticated stock the powers of control that he must have to be ultimately successful. There is no reason to assume that X-rays alone will do this thing: doubtless there are plentiful agencies, chemical and physical, which appropriately exhibited will do the same.

Advances in genetics in the more immediate future will be in the borderland of formal genetics and of developmental physiology. They will result from the deliberate and artificial induction of mutation and from the study of the gene in action. In this latter field the trail has been blazed by Goldschmidt and by Haecker Drosophila has served its purpose magnificently, but the time now approaches when other animals will usurp the centre of the genetic stage; experimentation will become more laborious, since each gene will have to be examined for the kind and rate of change which it produces. Geneticists, hearing of the vem discovered by Mendel, rushed headlong to this new Klondyke, avid for the gold of truth. They are now returning, some empty-handed, but many with nuggets of great worth. It will be well for biological science if those who resisted the call and stayed dutifully behind deny themselves the simple amusement of taunting the wanderer until at least they have assured themselves that nomadism of this kind must necessarily be profitless.

# Rationalisation in Industry.

FOR many reasons the introduction of scientific research into the old-established industries of Great Britain as an aid to production is a lengthy and difficult process. Much progress, however, has been made in recent years, notably with the aid of co-operative research associations, but much more remains to be done. The degree of interest in research shown by industries is a matter of concern to every scientific man, for an increasing appreciation of the potential industrial value of research spells more practical interest in the work of universities and similar institutions where pioneering investigations are carried out, and m-creased outlet for scientific employment.

How confidence can best be fostered is a matter of concern to many, and various ways have been tested or considered. Research is slow to fructify,

and industrial research may be especially so when the objective is restricted and definite. While broad researches are maturing the interest of the manufacturer may wane unless he have the stimulus of some accessory assistance. The successful solution by scientific research of a simple technical problem may be as convincing to a manufacturer as a far-reaching investigation of, say, the properties of his raw materials, necessary though that investigation may be. The simple problems cannot be ignored. Similarly, the demonstration of the utility of existing information is a valuable aid. There is much scope in industry for the increased utilisation of current information, scientific or otherwise, and valuable propaganda work can be accomplished by the organised collection and distribution of such information. In

this connexion a group of papers relating to information, organisation, and statistics in commerce and industry, discussed at the recent conference in Cambridge of the Association of Special Libraries and Information Bureaux, is of direct interest

The first paper in the group, dealing with rationalisation in industry, was communicated by Major L Urwick, honorary secretary of the Management Research Groups. The basic idea of the rationalisation movement is 'control' in the sense of "the detailed analysis and measured presentation of the facts in each and every set of circumstances—and the planning and organisation of future common action in the light of those facts " The movement is, in reality, an endeavour to develop the scientific habit of thought within industry and commerce. It insists that the phenomena influencing the course of business have each their cause, that the causes are capable of investigation and definition in the light of modern knowledge, and that the facts so gathered can advantageously be applied to the effective solution of fresh problems. Such an outlook must, as Major Urwick points out, be rationally applied to a manufacturing concern as a whole. It is useless, for example, to attempt to improve output by motion study among the operatives until the management, organisation, and planning of the concern as a whole have been put upon a sound basis; in the smaller industries, labour is often more conscious of mefficiencies than The objective should be a wellis management planned structure, strong, efficient, and co-ordinated in all its activities, and ever alert for improvement

In Great Britain the movement has recently found an outlet in the formation of the Management Research Groups. Co-operation is essential to the success of the movement, which calls for the free exchange of experience and facts bearing upon every aspect of industry. Each of the groups is a small band of representatives of manufacturing concerns in different industries. No two competing firms are represented in the same group, a compromise which meets the still existent feeling in favour of secrecy in industry. The firms in any group can investigate and discuss the best practice in each individual concern without fear of giving advantage to a trade rival. Major Urwick's survey of the need and scope for rationalisation in industry was of such great interest that it was to be regretted that time did not permit him to give a more detailed account of the progress of the Management Research Groups with which he is associated.

In the course of his paper, Major Urwick directed attention to the need for more and better coordinated statistics, in a later paper, Mr. A. E Overton, of the Board of Trade, described the trade information and statistics in Great Britain as compared with those in other countries manufacturers and traders are probably not fully aware of the sources of statistical information that are available, and to these Mr. Overton's paper will be of value reference is made to the time-lag in the issue of the statistical information from the various sources and the degree of classification adopted. Statistics of external trade and of internal production are of course of prime necessity in business forecasting, a subject discussed in the paper by Mr. W. Wallace. This paper outlines and illustrates the conclusions of the Harvard Committee on Economic Research; incidentally, it gives due weight to the limitations of business forecasting m its present pioneer stage. The paper by Mr. S. J Nightingale and Miss A. L Bennie dealing with statistical analyses in the engineering industry gives illustrative examples of the analysis of the available information in the formation of a sales A further example of the use of statistics in an industry was given by Mr. F. W. Tattersall, who discussed the relation of cotton statistics to marketing and market estimation, and the group of related papers was completed by Mr F. Hall's account of the more general aspects of the trade

At first sight the interest of such papers for a conference of the Association of Special Libraries and Information Bureaux is not obvious. The collation of sources of information, which is the chief function of the Association, should, however, render the latter almost essential to the rationalisation movement. The Directory of Sources of Specialised Information which the Association is shortly to publish will be of the greatest assistance to those who have to collect and collate the facts that industry needs. As an organisation for ascertaining and indicating where information is to be found, the Association should play a not insignificant part in the movement.

The movement deserves at least the benevolent interest of the scientific worker. It awakens in mdustry the scientific habit of thought; it encourages the wider dissemination of knowledge, including scientific fact, it fosters an increasing interest in, and appreciation of, science; if successful, it cannot fail to stimulate the utilisation of scientific research in industry.

# Obituary

Dr. D. G. Hogarth, CM.G.

BY the unexpected death of Dr. David George Hogarth on Nov. 6, geography and archæology lose one of their most distinguished representatives in Great Britain, and the University of Oxford one who combined in an unusual way the qualities of a student and a man of action and affairs. Born on May 23, 1862, at Barton-on-Humber, he was admitted commoner of Winchester in 1876, and elected to a classical demyship at Magdalen College, Oxford, in 1881, where he was placed in the first class in Honour Moderations and Literæ Humaniores, appointed to a classical lectureship, and then m 1886 elected to a fellowship. Both at school and at college he distinguished himself as a runner, and made himself felt in the social life of the place, presiding over the Junior Common Room, acting with the O.U. Dramatic Society, and editing the Oxford Magazine Of these early days he has left his own frank account in one of his most characteristic books, "Accidents of an

Antiquary's Life "

It was, indeed, a group of accidents that determined Hogarth's career The Craven Travelling Fellowship, of which he was the first holder in 1886, was itself an experiment in classical endowment, though the benefaction was an old one The new Lincoln and Merton professorship in classical archæology and art was maugurated in 1885 by Dr. (now Sir) W. M. Ramsay, who had begun m 1880 those journeys which revolutionised our knowledge of ancient Asia Minor had already been attracted by the historical and geographical achievements of Alexander the Great, and was collecting materials for his "Philip and Alexander," though this was not published until 1897. He seized the opportunity of apprenticeship to field work with Ramsay; and so began a partnership in research, all the more fruitful because the qualities of the two men supplemented each other. As one of the first students at the newly founded British School of Archæology at Athens, he took a leading part in excavating the famous Temple of the Paphian goddess in Cyprus. First fruits of this adventure and of an extensive tour in unfrequented parts of the island were published m 1890 under the title of "Devia Cypria" In Cyprus, then, and Asia Minor, he began that intimate acquaintance with the peoples and problems of the Near East which led him afterwards to Deir-el-Bahari, Naukratis, and Carchemish, to North Arabia, and the 'Arab Bureau' in Cairo.

To combine these vacation pursuits with the routine of a college dean and vice-president was not easy. "Philip and Alexander" had to await the convenience of Turks and undergraduates; but with wise economy of resources Magdalen created a research fellowship, and made Hogarth master of his time and movements, with an Oxford home in which to store and work up his materials. Fortunate again in his opportunities, he was Director of the British School at Athens, and in charge of excavation on the prehistoric site at Phylakopi in Melos, during the years when Crete fell free of Turkish rule and excavation became possible there; and in the early years of Sir Arthur Evans's great enterprise at Cnossus, Hogarth was engaged in opening tombs hard by, and in exploring the important and difficult 'Cave of Zeus' on Mt. Dicta, and the remote but significant site at Zakro, looking out over the ancient sea route to Egypt. Emergency work at Naukratis, rendered necessary by the extension of irrigated land in the Delta, took him in 1899 and 1903 to Egypt, where he had already excavated at Deir-el-Bahari in 1894, at Alexandria in 1895, and in the Fayum in 1896. Then came the British Museum's excavation of the Temple of Artemis at Ephesus in 1904-5, with unforeseen difficulties from flood and fever, and no less unforeseen results in the splendid foundationdeposit of early goldwork and ivories, throwing quite new light on early Ionian art and culture. These were published in a stately memoir in 1908,

and interpreted in larger historical perspective in "Ionia and the East" in 1909 After another season in Egypt, at Assiut, came another chance to break fresh ground, at Carchemish on the Euphrates, again for the British Museum, with assistants of his own training, T. E Lawrence and C. L Woolley, both destined to notable achievements later

Meanwhile a fresh line of work opened in 1909, when Sir Arthur Evans resigned the keepership of the Ashmolean Museum, which he had re-created as a centre of prehistoric and oriental studies. Hogarth was the obvious man to succeed him, and the peculiar combination of facilities for home study and field work which the keepership offers, happily provided for him the post which he held until his untimely death. He retained his Magdalen fellowship, and took an ever-increasing part in University affairs, on the Hebdomadal Council, the Clarendon Press, and (later) the Statutory Commission; and it was at one time hoped that he might represent the University in Parliament.

Across these many activities, and still more across his archæological work, broke the Great War. Hogarth had intimate knowledge of Turkish and Arab ways, and was able to render most valuable services in organising and directing that 'Arab Bureau' in Cairo which prepared the way for attacking the Ottoman Empire at its weakest point, through that 'Revolt in the Desert,' in which T. E. Lawrence was his own discovery. At the Peace Conference he represented Great Britain in the Middle East Commission, and maintained the keenest personal interest in the new regime and its problems. For these public services he was honoured with the C.M.G., and Egyptian and Arab decorations. His wide and detailed knowledge of Arabia and the neighbouring lands was recognised already by the award of the Founder's Medal of the Royal Geographical Society, and assured his election as president of that Society in 1925.

With these numerous calls upon his time and great abilities, Hogarth's output of scientific work was less abundant and consecutive than those who best knew his fine scholarship, wide learning, and literary facility, had reason to expect he neglected the prompt and detailed publication of his numerous pieces of field work and excavation —though this was not the side of the business that best pleased him. But, naturally laconic, and clear-headed, he wrote concisely, and without parade of information, beyond what was essential to his point. He had, moreover, a journalistic—or was it rather Herodotean—appreciation of episodes and situations, vividly revealing "all the kingdoms of the world in a moment of time," and some of his best remembered writing deals with incidents of this kind. But for a man of these wide interests "the world is so full of a number of things," that a lifetime passes all too soon, in 'Forschungen' and 'Prolegomena,' not to mention the "History of the Air Force," which he inherited from his friend Sir Walter Raleigh, and a projected life of 'Arabian' Doughty, another of his heroes. "Alexander" seemed always to have to wait.
What will be remembered, however, besides

Hogarth's brilliant summaries of geographical and historical knowledge, "The Nearer East," "The Penetration of Arabia," "The Ancient East," and The Balkans," is his monumental catalogue of the "Hittite Seals" of the Ashmolean Museum (1922), and the numerous short articles which announced, interpreted, and thereby in a very real sense guided the progress of discovery in the difficult history and ethnography of Asia Minor and North Syria. Though he never brought his materials together into a general survey—for which, indeed, the time is scarcely yet come—this group of problems was

that to which his mind seemed most spontaneously to recur; to which he gave all time spared from the more urgent 'accidents' which beset a 'wandering scholar', on which his judgment was most in demand among colleagues who had not his distractions and occasions. Had he entered the army (as at one time he desired), Hogarth might have been a great commander, for he could handle men, and his decisions were those of a 'cavalry-mind.' In his actual career he was a superb scout, with a general's outlook over the prospects and trend of exploration J. L. M.

# News and Views.

The appearance of Prof C. T. R. Wilson's name in the list of Nobel prize winners for 1927 will be received with acclamation by physicists throughout the world. The polished perfection of his experimental work and the subtle ingenuity of his methods have long been the admiration and the despair of workers in the same or in cognate fields Prof. Wilson is, perhaps, best known for his experiments on the tracks of ionising particles in gases, work which has occupied him, at intervals, from the time when he joined the first group of research students under Sir J. J. Thomson, some thirty years ago. His discovery that gaseous ions would serve as nuclei for the deposition of water drops was the basis of the first methods of measuring the charge on an electron. With definite patience and resource, the technique of these early experiments has been gradually perfected, until now it is possible to make visible, and to photograph, the actual tracks of ionising particles, to count their number, and to watch every twist and turn in their paths. The power of rendering visible, at will, the actual paths of particles which, themselves, must remain for ever invisible is a weapon of no small value in investigating the behaviour of these particles, and Prot. Wilson's apparatus is being employed more and more in our great research laboratories, almost always with striking and important success. Prof. Wilson, however, is not known only by his work on 'tracks.' He is one of our foremost experts on atmospheric electricity; and it would be both unfair and ungrateful not to recall in conclusion his 'tilted' electroscope, a measuring device which made possible much of the early work on ionisation in gases.

Prof Arthur Compton, of Chicago, who divides with Prof. Wilson the Nobel prize for physics for 1927, belongs to the younger school of American physicists, and has distinguished himself by the daring originality of his speculations, as well as by the variety and ingenuity of his experiments. Adopting the new 'quantum' theory in its most extreme form, he was able to calculate the change in wave length which should occur when X-rays are scattered, and by very able experimental work to obtain confirmation of his calculations. The technique of these experiments was so difficult that it was some time before the results were confirmed by other workers, and some controversy arose as to the genuineness of the effect. In the

end, however, the Compton effect was finally established, and it stands to-day as the firmest individual piece of evidence in favour of the hypothesis of localised light quanta.

THE recent judgment of the Court of Appeal in Inland Revenue Commissioners v. Yorkshire Agricultural Society, before the Master of the Rolls, Lord Justice Atkin, and Lord Justice Lawrence, is significant as indicating the confusion and difficulty prevailing in interpreting what is or what is not a 'charity within the meaning of the Income Tax Acts. The Commissioners had refused the claim of the Society to exemption, whilst on appeal to the Special Commissioners the claim was allowed. Mr Justice Rowlatt in the High Court afterwards reversed the decision of the Special Commissioners; and now the Court of Appeal unanimously affirms the Special Commissioners' decision. In giving judgment for the Society the Master of the Rolls referred at length to the objects for which the Society was established, pointing out that it was formed at York in 1837 for the purpose of holding an annual meeting for the exhibition of farming stock and implements, etc., and for the general promotion of agriculture. Prizes were awarded, and the members enjoyed certain privileges and benefits. The privileges and benefits which the members derived did not, in his loidship's opinion, in any way detract from the fact that the purpose of the Society was charitable within the meaning of the Act, any more than the privileges and benefits which subscribers to other charities, such as hospitals, derived, altered the fact that they were charities. He held that this Society, which by its constitution in 1837 and since had continued for the purpose of the general improvement of agriculture and not merely for the special benefit of its members, was in fact a society for the general benefit of the community, and therefore came within the accepted definition of a charity as laid down by Lord Macnaghten (Income Tax Commissioners v. Pemsel, 1891). This decision should help to define the position of scientific societies in regard to exemption from income tax, for they should be able to establish, by their constitution and the aims and objects of their work, those elements of permanency and benefit to the community that the Yorkshire Society has claimed and won for agricul-

Prof. W A Bone's researches on high-pressure gaseous combustion which, with the collaboration of assistants, have been carried on since 1920 at the Imperial College of Science and Technology, London, have become so well known, and have so direct a bearing on new developments in chemical industry, that the extension of the work and the occurrence of greater opportunities for training in its special technique will arouse more than local interest. A generous donation and annual grant by Imperial Chemical Industries, Ltd., together with increased assistance from the Department of Scientific and Industrial Research, have supplemented the funds already supporting the investigations, making possible the equipment of two new high-pressure gas research laboratories, including an experimental gas-generator plant, gas-holders ranging in capacity from 10 to 3000 cubic feet, and compressors The explosion bombs will be capable of withstanding pressures ranging from 100 to 20,000 atmospheres, respectively, and the catalytic-tube units will withstand 500 atmospheres at 500° C. By the end of March 1928, most of the new equipment will, it is expected, be ready for operation, and a limited number of selected postgraduate research students (early application regarding the vacancies being advised) will be accepted for systematic training over a period which will usually be not less than two years. The staff will consist of four research assistants, an instructional assistant, and a mechanical assistant; the work will be directed by Prof. Bone, assisted by Dr D. M. Newitt and Dr. D T. A. Townend, and by Mr W. E Stockings.

A DISPATCH from the Cairo correspondent of the Times which appeared in the issue of Nov 9 describes some of the results obtained by the excavations at Sakkarah, where work has now been resumed for the season. The excavations, which began in 1923, are being carried out under the direction of Mr. Cecil Firth for the Egyptian Department of Antiquities. They have opened up an entirely new chapter in the history of Egyptian art and architecture, and may be expected to lead to even more important results in the near future. In carrying on the clearing of the Temenos surrounding the Step Pyramid, which was begun in 1926, it was discovered that at one point where the Temenos wall was higher it formed the superstructure of a tomb which proved to be of the III Dynasty, and must have belonged to a member of the Royal family or an important personage of the court. Access was obtained to the tomb after immense labour by means of a plunderer's shaft in the rubble and giving access to a rectangular space cut in the rock, and a stairway leading at a distance of twenty yards to a doorway beyond which the stairway continued. This passage, after passing two sets of chambers, eventually reached one of the most extraordinary funeral apartments ever found. So far as explored it has two rooms which were entirely lined with blue tiles. In one room, three doors each had exquisite reliefs of King Zoser wearing the red or white crown. The tiles were arranged to give the impression that the rooms were lined with reed mats, placed vertically, except over the panels of the doors and the drums over the doorways where they are horizontal, and give the appearance that the mats are rolled up to reveal the rehefs. A series of passages behind leads to a pit filled with debris, upon which work is now being concentrated.

Cod-Liver oil has for long been considered the most potent source of the two fat soluble vitainins A and D. but, though palatable to some, to others it possesses an unpleasant flavour which is only imperfectly disguised even when the oil is mixed with The discovery by Rosenheim, extract of malt Webster, and Windaus (Lancet, 1927, vol 1 p. 306, and NATURE, Sept 24, p. 440) that the parent substance of vitamin D (the antirachitic vitamin), from which it is formed by the action of ultra-violet light, is ergosterol or a highly unsaturated sterol of similar constitution, opened the way to the production of this vitamin on a large scale, under controlled conditions, and without the necessity of using codliver oil at any stage, since the ergosterol can be obtained either from ergot or yeast as a pure chemical compound. Although vitamin D is specific in its effect in ensuring proper calcification, its absence from the diet leading to the development of rickets, yet in its influence on growth it is associated with vitamin A: the latter is probably of the greater importance in this connexion, but its full effect in producing growth in the young animal is not observed unless vitamin D is also present. For this reason vitamin D alone would be of less general use than if accompanied by vitamin A.

THE British Drug Houses, Ltd., London, N 1. have taken advantage of the recent advances m our knowledge of the vitamins to put up preparations containing vitamins A and D obtained from sources not previously utilised. Vitamin D is made by the irradiation of ergosterol, and is issued under the name 'Radiostol' in solution as a sweetment pellet. Vitamin A is contained in an oil not previously used as an accessory food: it is issued, combined with vitamin D, as an oil called 'Radiostoleum.' The latter is also issued as an emulsion, 'Radiomulsin,' and as an emulsion with malt, 'Radio-Malt,' in which the malt extract provides also a supply of vitamin B. The vitamin content in these different preparations is controlled by physiological feeding tests on animals, and is higher than in cod-liver oil and its various preparations.

The Slutzk, better known under its original title, Pavlovsk, Observatory for meteorology and geophysics, will celebrate on Dec. 4 the fiftieth anniversary of its foundation. Well equipped with magnetic instruments designed by its eminent first director, H. Wild, and for many years the most northern magnetic observatory in the world, Pavlovsk has supplied a long series of valuable magnetic results, which have been utilised in many researches by foreigners as well as Russians. Observations in atmospheric electricity, begun in 1913, have supplied data of much interest in connexion with the vexed question of the true nature

of the durnal variation of the potential gradient Actinometry has also had a special place in the programme of the observatory during the present century Aerological work in Russia had its origin at Pavlovsk some thirty years ago, but it is now provided for in a separate institution. Foreign participation is invited in the approaching ceremony.

An interesting biographical sketch, by Mr Rollo Appleyard, of Heinrich Hertz, one of the greatest pioneers on the transmission of electrical waves, appears in the October number of Electrical Communication. At the age of twenty-three years, Hertz was elected a demonstrator in physics by Helmholtz Three years later he became a lecturer in theoretical physics in the University of Kiel. After two years at Kiel he became professor of experimental physics at Karlsruhe, and finally he was appointed to succeed Clausius as professor of physics in the University of Bonn. His wonderful experiments on the reflection, refraction, and polarisation of electric waves created intense interest at the time and opened a new field of research. They form the foundation on which most of present-day developments on radio communication are based. The author gives photographs of Hertz's original apparatus and of the devices he employed to produce and to detect the electric waves. He points out how nearly Hertz and his colleague Lenard anticipated the discovery of Rontgen rays. Hertz himself thought it unlikely that electric waves through space could be used for communication He died at the early age of thirty-seven. Those who knew him best remember him as a singularly modest man, one who seldom spoke of his own discoveries and never mentioned himself. When the Royal Society presented him with the Rumford medal, he silently disappeared from Bonn for a few days, giving no reason for his absence. He studied pure science exclusively, and yet the importance of his discoveries in the advancement of the practical applications of electricity is beyond measure.

Opinions may differ about the ethics of greyhound race-courses, but it seems likely that this form of sport will become as popular in Great Britain as it has already become in the United States. In the Metropolitan-Vichers Gazette for October, a good account is given of the electrical equipment of a greyhound racecourse. All around the course, which is 500 yards long, a sunken trackway is constructed in which a narrow-gauge railway is laid. The trackway is covered, but an opening in the woodwork is left on the side nearest the course. Through this opening an arm projects which carries an artificial hare. The arm forms the axle of a rubber-tyred wheel above which is the hare. It is attached to an electrically-propelled truck which collects the electric current from a third rail and returns it by the ordinary rails. Special precautions have to be taken to avoid sparking, which might disturb the dogs. Acceleration and deceleration have to be very rapid and high power is therefore necessary. The running of the truck is controlled by a single operator from a control tower observation room, so situated that a full view of the racing can be had at all times. Speeds up to 50 miles per hour are obtained, and the hare must be capable of being accelerated at a rate of not less than 2.5 miles per hour per second. When a race takes place the hare is run round the track, and immediately it has passed the boxes where the greyhounds are confined, the gate is thrown open and the dogs dash out in pursuit. The attendant keeps the hare ahead of them until the circuit is complete and then switches the truck into a siding. This causes the hare to disappear and the dogs cease to run. The Company mentions ten large towns in Great Britain for which it has supplied or is supplying the electrical equipment for the tracks.

In order to lower the price of electricity it is necessary to have all the machines in a power station running for as long a period as possible. To enable this to be done it is advisable that engineers should encourage a night load on their stations. One way of doing this is to store up energy in consumer's houses during the night time which can be utilised during the day. One of the best ways of doing this is to heat water slowly during the night by electricity, the warm water being utilised during the day. This is already done on a large scale in several places in Great Britain and abroad In Basle there is a thriving industry in making electric water heaters and time switches. These heaters work only between 10 P.M. and 6 A.M., the switching being done automatically The results obtained prove that this domestic storage is a boon to the consumer and is profitable to the electric supply company. The Glasgow Corporation is also encouraging domestic storage. Electricity is supplied for this purpose at the very low rate of 3ths of a penny per unit. The heat losses from a well-designed electric heater are so small that the consumer is scarcely affected by them In another system, used abroad, each room of the house contains a 'heat-accumulation' stove. Each stove contains steatite blocks of high specific heat which are heated by cheap night energy. When taking energy during the night a damper at the top of the stove is kept closed. In the morning, or whenever necessary, this is opened and convection currents circulating upwards heat the room. Another system of storage heating for large buildings is to have heating elements embedded in concrete floors. A full description of these and other methods is given by L. G. A. Sims in a series of articles in the Electrical Review, beginning in the issue for Oct. 21.

In travelling about the country, especially, but not entirely, in out-of-the-way fishery districts, fishery enthusiasts, both amateur and professional, are frequently met with, demanding information on fishery problems, whether these relate to fish in a zoological sense, or 'shellfish.' The Fisheries Branch of the Ministry of Agriculture and Fisheries is now making efforts to form what is, in effect, a British Fisheries Information Bureau in embryo, by supplying information (free on application to the Fisheries Secretary, 43 Parliament Street, London) in a series of numbered Fisheries Notices, which are small pamphlets dealing in a popular manner with fishery

problems on the biology and or economic aspects of particular freshwater and marine fish and 'shellfish.' There remains, however, a lot of ground to be covered before the Fisheries Branch can be regarded as having supplied inquiring fishery interests, with not only that which is known, but also in many cases that which is not known, and the department concerned may reasonably be urged to speed up its work So far the subjects dealt with are, respectively: No 3, Precautions re installing motor power in fishing vessels; No. 4, Value of the herring as good; No 5, Instructions for taking water samples in cases of pollution of fisheries; No 6, Particulars of publications about all fishery matters; No. 7, Instructions for cooking salted herrings, No. 8, Methods of preparing and cooking freshwater fish; No. 9, On the capture of freshwater eels; No 10, About the marking of fish; No. 11, On sheep-dips and sheepdipping; No. 12, The life-history of the place; No. 13, Mussel cultivation; and No. 14, Cockle culture.

Fisheries Notices, No. 13 and No. 14, are new, and both contain interesting and informative short chapters on natural history, methods of fishing, cultivation, destructive influences and animal foes and parasites, economic uses, and also-a subject on which the Ministry can speak with authority—on pollution and purification. In both cases the account of the natural history would have been improved if it had been explained that, in spawning, the eggs are shot out of the shell, and not retained as they are in the English oyster (O. edulis) and some freshwater pearl mussels (e.g. Anodonta). Similarly, in the chapters on cultivation, the practical value of simply transplanting young individuals from situations high up in the tidal zone to lower ones, chosen with circumspection, might have been stressed to greater advantage. The mussel and cockle are, however, of relatively small value compared with the oyster, lobster, crayfish (Palinurus), and the various dog-fishes, about all of which the dissemination of information would be of undoubted economic value to many interested in fisheries. It is to be hoped that the Fisheries Branch has in view the issue of additional pamphlets on these subjects in the near future.

Though the problem of providing adequate indexes to scientific and learned books and journals is ever to the fore and is constantly engaging the attention of the various professional bodies concerned, the old idea that indexing is essentially the work of the unskilled drudge has not been entirely eradicated. It is now proposed to form an Institute of Indexing, the main objects of which will be to encourage the compilation of efficient indexes to books, periodicals, and other literary works and papers, and to promote their intelligent use by the public, to maintain a register of qualified indexers, and generally to give advice and assistance wherever needed. It is not apparently intended that the Institute should follow in the footsteps of the old Index Society and devote itself to the actual compilation of indexes, but that primarily it should act as a trade union to represent qualified indexers in all matters affecting their status and recognition as members of a 'key' profession. The organisers are ambitious enough to hope that there will be a grade of 'fellows' confined to fully qualified indexers, and one of ordinary members for those interested from the users' point of view or who wish to avail themselves of the advisory and other services of the Institute Particulars may be obtained from Mr. W. R. Douglas Shaw, "Beautort," Mornington Road, Chingford, London, E.4.

PROF. W. A BONE will deliver a lecture entitled "Gaseous Combustion at High Pressures," in the rooms of the Chemical Society, Burlington House, on Thursday, Nov. 24, at 8 P M

SIR ARTHUR KEITH, president of the British Association, will take the chair at the third annual Norman Lockyer lecture, "Scientific Ethics," to be delivered by the Very Rev Dean Inge, in the Goldsmiths' Hall on Monday, Nov. 21, at 4 P.M

PROF E. T. WHITTAKER will deliver a lecture at the meeting of the London Mathematical Society on Thursday, Dec. 15, at 5 p.m., in the rooms of the Royal Astronomical Society, Burlington House. His subject will be "The Influence of Gravitation on Electromagnetic Phenomena." Members of other scientific societies are invited to attend.

The maugural meeting of the British Institute of Radiology, with which the Rontgen Society is now incorporated, is being held on Nov. 17 and 18, and is the first meeting of the reconstituted body. The meeting thus marks the commencement of a new era in the history of radiological organisation in Great Britain.

Three earthquakes of moderate intensity were recorded at Kew Observatory on Nov 14. The times of arrival of the first phases were 0 hr. 21 min 25 sec., 5 hr 5 min 49 sec., and 7 hr. 33 min 21 sec G M.T. The second earthquake was a repetition of the first, and the epicentre is estimated to have been 3680 miles away, probably in the Arctic Ocean. The epicentre of the third disturbance was at a distance of about 6300 miles.

The following officers and new members of council of the London Mathematical Society were elected at annual general meeting held on Nov. 10: President: Prof. G. H. Hardy; Vice-Presidents: Prof. A. S Eddington, Mr. R. H. Fowler, Prof. G. B. Jeffery, Treasurer. Dr. A. E. Western; Librarian: Prof. H. Hilton; Secretaries: Prof. G. N. Watson, Mr. F. P. White; New Members of Council: Prof. P. J. Daniell, Mr. A. E. Ingham, Dr. E. G. C Poole.

APPLICATIONS for grants from the Chemical Society Research Fund must be received, on a prescribed form, by the Assistant Secretary of the Society, Burlington House, W.I, not later than Dec. 1. The income arising from the donation of the Goldsmiths' Company is more or less especially devoted to the encouragement of research in morganic and metallurgical chemistry. The income from the Perkin Memorial Fund is applied to investigations relating to problems connected with the coal-tar and allied industries.

MESSRS. J. and A. Churchill, the well-known firm of medical and scientific publishers, have removed from Great Marlborough Street to 39 and 40 Gloucester Place, Portman Square, London, W.1. The firm was founded in 1825 by the grandfather of the present partners, the late John Churchill, and since 1845 it has published "The Medical Directory." Its list of authors includes leading representatives of many departments of science.

WE have received from Mr. W. H. Harling, 117 Moorgate, London, E.C.2, copies of two recent sectional catalogues of drawing instruments, most of which are manufactured by the firm at the Grosvenor Works, Mount Pleasant Hill, London, E.5. Catalogue No. 5c deals with compasses, dividers, and similar instruments, both singly and in sets. The 'British Empire' (B.E.) series of instruments are made of hard-drawn electrum and fitted with stainless steel ink points; the compasses are provided with self-centring head-joints. Catalogue 8b is devoted to drawing scales and boards, T-squares, etc.;

it includes particulars of slide-rules, planimeters, and integrators of special patterns, as well as instruments made by the firm.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned .- Fulltime teachers of carpentry and joinery, carving and modelling, and of pharmacy, in the Leicester Colleges of Art and Technology-The Registrar, Colleges of Art and Tethnology, Leicester (Nov. 30). A senior lecturer in the department of pure and applied science of Loughborough College-The Principal, Loughborough College, Leicestershire (Dec. 1). A mathematical master at the Royal Naval College, Dartmouth —The Headmaster, Royal Naval College, Dartmouth (Dec. 15). An officer with experience of plantation work to take charge of the Oil Palm Plantation of the Government of Sierra Leone—The Private Secretary (Appointments), Colonial Office, 38 Old Queen Street, S.W.1. A head of the Arts department of the Portsmouth Municipal College—The Secretary, Office for Higher Education, Municipal College, Portsmouth.

### Our Astronomical Column.

THE TRANSIT OF MERCURY.—Fine weather favoured this phenomenon in most parts of England, and a large number of observers made successful observations The planet appeared as a well-defined black spot, decidedly darker than any of the umbræ of the large sunspot group that was nearly central on the disc No trace was seen of any luminous ring round the portion of the disc that had passed off the sum at egress Definition was not very good owing to the low altitude; consequently there is a range of many seconds in the times of contact given by different observers It is most convenient to give the times as corrections to the predicted times, which were 8h 28m 23s 9 for third contact, and 8h 30m 5s 2 for fourth contact for London and neighbourhood. Mr. L. G. Guest, observing with an 8½-inch refractor at Ferring, Sussex, found the corrections - 25<sup>s</sup>·9 and - 30<sup>s</sup> 2. Mr. A. F. Bennett, observing with a 6-inch refractor at Leiston, Suffolk, found corrections –  $15^8 \cdot 3$  and –  $29^8 \cdot 2$  Dr. A. C. D. Crommelin, observing with a 3-mch refractor, power 40, at Blackheath, found - 33s and - 48s. The last are undoubtedly too early, the power being inadequate for accurate observation. The fact that the contacts happened some twenty seconds ahead of calculation is confirmed by other observations; a similar result was obtained in the 1924 transit; this is the direction to be expected if the unexplained lunar irregularities are due to change in the rate of the earth's rotation. It is noteworthy that observations have been obtained in England of all the four transits in the present century.

NAKED-EYE SUNSPOT.—The appearance of a large group of sunspots near the sun's central meridian was noted by observers of the transit of Mercury on the morning of Nov. 10 By the following day the group had increased perceptibly, and it became a naked-eye object for two or three days, after which its approach to the west limb with consequent foreshortening prevented its being seen without slight optical aid. A photograph taken on Nov. 6 shows the group commencing as a small spot in some faculæ which could be identified with an earlier group of spots in the preceding rotation. The increase in the size of the spots and their changes in structure between Nov. 9 and 12 denoted considerable activity. The

magnetograph traces at Greenwich show, however, no unusual disturbance of the magnetic elements. Other particulars of this group of spots are given below.

The Nucleus of Comet Pons-Winnecke.— L'Astronomie for October contains an interesting drawing of this comet made by M. F. Baldet with the great Meudon refractor at the time of its near approach to the earth last June. His photographs appeared in the September issue, but they were on an insufficient scale to bring out the extremely small size and sharpness of the stellar nucleus. The drawing is on a scale of 1 inch to 4"; it shows a well-defined central nebulosity 2½" in diameter, with a very minute stellar point in the centre. The latter was too small to measure, but M. Baldet estimates that its linear diameter did not exceed 400 metres. It presumably consisted of a compact swarm of meteoric masses. It is a matter of surprise that these have retained their compact formation for more than a century (the comet was first seen in 1819), in view of the large perturbations by Jupiter that it has experienced on several occasions.

A few weeks ago comment was made in this column on the compactness of the meteoritic swarm that is supposed to have formed Meteor Crater in Arizona by impact with the earth. The central portion of the present comet, if we accept M. Baldet's estimate of its size, seems to be of comparable dimensions. M. Baldet goes on to comment on the difficulty of supposing that such compact swarms are of great antiquity, and directs attention to the theory (first seriously proposed by R. A. Proctor) that the short-period comets are the products of eruptions from Jupiter. In this comnexion it is interesting to note that the astronomers of the Jungfrau observatory report an interesting outburst on Jupiter on Oct. 11. A small bright spot suddenly appeared in the equatorial zone (having somewhat the appearance of a satellite in transit). It seems to have disappeared after a short time; but the details to hand are telegraphic and meagre.

No. 3029, Vol. 120]

# Research Items.

TOTEMISM IN SOUTH AMERICA.—Mr. R E Latcham, for many years a resident in Chile and a student of the history and ethnology of the Indian tribes at present inhabiting the Andean area and their predecessors, has made an exhaustive study of a mass of unpublished material stored in Spain and in South America, much of which has never been examined before from the point of view of the anthropologist. Many of these documents, especially the grants of Indians to the early Spanish colonists, recite details relating to the tribes which have provided evidence throwing an entirely new light, Mr. Latcham maintains, on the organisation and beliefs of the early Andean peoples. A study of their totemism based upon this material is published in the Journal of the Royal Anthropological Institute, vol. 57, Part 1 From this that appears that not only was descent matrilineal, contrary to what has been believed, patrilineal descent being introduced later under Spanish rule, but also their toternic system differed essentially in certain important respects from the standard system of other continents, though it presents close affinities with the system of North-West America The tribe was not descended from the totem, although they called themselves children of the sun, the lion, and so on. They had a common ancestor who had a separate cult from the totem, but to whom the original totem was ally and blood brother. Only occasionally was the totem an animal or plant, celestial bodies, natural phenomena, geographical features, and manimate objects were also chosen. These latter, however, might have a symbol; e.g. the falcon, eagle, and bustard were symbols of the sun, taking its place in many rites and ceremonies. sun, it now appears, was the totem of a special and powerful clan widespread over the country, and not the symbol of the Incas generally. The totem when an animal was sometimes, but not always, taboo. It might, especially in the coastal region, be chosen from among the annuals or articles which formed the staple diet of the tribes. Sometimes the totem was an animal having a special mark or defect. During ceremonial dances, the dancers dressed in the fur or feathers or some article symbolic of the totem. As a rule clans were exogamous.

TELEGRAPHISTS' CRAMP.—In 1922 the Industrial Fatigue Research Board was approached by the Union of Post Office Workers with a request to investigate the subject of telegraphists' cramp. resulting investigation (Medical Research Council, Industrial Fatigue Research Board, Report No. 43: A Study of Telegraphists Cramp. By May Smith, Millass Culpin, and Eric Farmer: H.M. Stationery Office. 1s. 6d) was directed towards finding "whether, and how far, there is a specific susceptibility A comparison was made between two groups. telegraphists certified as suffering from cramp, and others apparently free from it. Certain psychological others apparently free from it. Certain psychological tests involving speed and accuracy of movement were applied to both groups (test of pressure exerted, the ergograph test, and the McDougall-Schuster dotting test), and it was found that, with certain exceptions, the telegraphists in the non-cramp group showed better records than those in the cramp group. The subjects in both groups were then studied, with special reference to the presence or absence of psycho-neurotic symptoms. Again the two groups were not completely differentiated, but 75 6 per cent. of the cramp cases showed symptoms of psycho-neurosis, while of the non-cramp group 32.5 per cent. had these symptoms. The tests were repeated with a group of a hundred learners at the school of telegraphy, and it was found that amongst these the 'cramp type' could be differentiated. The working efficiency of the learners (based on the opinion of a superior officer) showed some relationship to their ability at the tests. Finally, a study of the psycho-neurotic symptoms of certain control groups was made, which suggested that the incidence of these symptoms among telegraphic workers was approximately normal. It appears, from the results of the research, that some preliminary selection of telegraphists by tests and examination would reduce the medence of cramp.

Pennatulids of Japan.—Prof. J. Arthur Thomson and Miss Nita J. Rennett, in their report on the collec-Japanese Pennatulids from Japanese waters ("Report on Japanese Pennatulids." Journal of the Faculty of Science, Imperial University of Tokyo. Section 4. Zoology, vol. 1, Part 2, 1927), record 24 species, none of which was not better the school of the section of of which is new, but they show interesting variations among the commoner forms, and valuable notes are given on those which are less well known. Three beautifully coloured plates show complete specimens of six species with details of others. Figures of spicules are given in the text. These spicules, absent in only a few forms, are some of the chief characters used to distinguish the species, genera, and even families. It is a vexed question whether to place the genus Scytalium in the family Virgulariidæ, the Balticinidæ, or the Pennatulidæ. The authors have solved the problem by creating the new family Scytalidæ, which agrees with the Ponnatulidæ in having pronounced pinnules but differs in having the spicules small and oval instead of three-flanged, whilst it is removed from the neighbourhood of the Balticinida and Virgulariidæ, which are without very pronounced pinnules. Anthoptilum thomsoni, which is figured in colour, natural size, is regarded as a species distinct from A. grandsforum, with which it was merged by Hickson and Kukenthal It is described as a "large, magnificent Pennatulid," measures 94 continuetres, and differs in many respects from A grandsforum. It has been previously recorded from the Atlantic, south of Buenos Ayres, at 600 fathoms.

REPRODUCTION IN UALANUS FINMARCHICUS.—Dr. G. P. Farran has recorded interesting observations on this important copepod (*Jour. Con. Internat. Explor. Mer.*, vol. 2, No. 2, 1927. "The Reproduction of Calanus finmarchicus off the South Coast of Ireland ' Investigations were undertaken by the Department of Fisheries of the Irish Free State and its predecessor the Fisheries Branch of the Department of Agriculture and Technical Instruction. A special area was chosen and samples taken at intervals from 1913 to 1924, a Nansen net of standard silk No 3 with a ring of 50 cm. diameter being used, hauled by a hand winch at an average rate of between 3 and 4 metres per second, and the total number of Calanus present and the proportions of the successive developmental stages estimated. Nauplii as a rule escaped through the meshes, therefore the copepodite stages only were noted (Stages I to VI, the sixth being the adult form). average catch for each month in a vertical haul from bottom to surface shows that April is the maximum month and March the minimum, although very few specimens were caught from September to February. The number of specimens in each month range from 75 to more than 34,000. There are, however, only few adults compared with the numbers of immature forms. Calanus finmarchicus in the area examined passes the

winter mainly in the late copepodite stages, then becoming adult in January, February, and Maich, but meantime the total stock diminishes rapidly, reaching a minimum in March. In April reproduction, which has already begun in March, is at its height, and is still going on in May, after which the numbers fall off gradually until September Calanus may reproduce irregularly all through the summer, and a few early stages may still be found in the autumn. The only record for January shows that there was a very large preponderance of males, chiefly in Stage V in 1921, females predominating in all the other months, adults especially in February and March. In April, Stages II and III, June to July, Stage IV; August, IV and V; September and November, VI. The author thinks it is probable that adults of the previous year do not live beyond April and May, their places being taken by specimens hatched earlier in the year which have rapidly gone through their metamorphosis. In the autumn the growth appears to be much slower; months instead of weeks being necessary to complete the development.

Useful Extracts from Japanese Forest Trees,—In the Journal of the College of Agriculture, vol. 9, No. 2, Imperial University of Tokyo, Ihachiro Miura gives some of the results of three years' labonious work on the determination of 'useful matters' contained in the forest trees of Japan. More than 100 species have been examined and analysed, and the results, given in tabular form, will form useful data for industrial chemists engaged on problems connected with plant products. The work is divided into six parts as follows: (1) Fatty oil contents in seeds of various forest trees; (2) contents and properties of tung oils from various species; (3) tannin contents in various forest trees; (4) the content of the methoxyl group in the principal forest trees, and its utilisation by dry distillation; (5) the growth of cinchona in Formosa and its alkaloid content; (6) the needle oils from coniferous trees.

THE CALCIFUGE HABIT IN MOORLAND PLANTS .-The occurrence of moorland plants on 'sour' or lime-deficient soils and their absence from calcareous soils has presented a problem of perennial interest to field botanists. W. H. Pearsall and Marjory Wray have investigated the problem in the case of Errophorum angustifolium in terms of (1) the calcium content of the soil solution, (2) its basic ratio, i.e. (K+Na)/Ca, and (3) its hydrogen ion concentration (Journal of Ecology, vol. 15, No. 1). These factors were controlled by using variations of Shive's threesalt culture solution as rooting media. The constituent elements of the solutions were varied in concentration within certain definite limits, and the effects on the growth and form of the culture plants were noted. In general, the effect of high calcium content in the culture solutions was a pronounced tendency to lowering of the water content of the plants as expressed in the ratio of fresh weight to dry weight. When the basic ratio was high, however. the effect of calcium was reduced. Change of acidity in the medium altered the calcium absorption, which was high when the hydrogen ion concentration was in the vicinity of pH 7, low in the region of pH 45. In a series of germination experiments it was found that in relatively acid media (pH 45) the most rapid germination took place in solutions relatively rich in calcium, while in neutral solutions (pH 7) germination was most rapid in media containing smaller quantities of calcium. These conditions are explained on the basis of the effect of hydrogen ion concentration on calcium absorption.

That climatic conditions may act as factors modifying the effects of calcium is indicated by varying the temperature and atmospheric humidity conditions of the experiments. Calcium effects were accentuated by low temperatures and dry atmospheres and decreased by the opposites. Under natural conditions similar effects seem to obtain. Analysis of soil waters showed concentrations of calcium and potassium similar to those used in the experiments.

EXTRACTION OF SUGAR FROM BEET.—An illustrated account of the various processes in the sugar beet factory at Poppleton, Yorks, is given in the *Journal* of the Ministry of Agriculture (vol. 34, p. 612). This factory, elected in the summer of 1926 by the Anglo-Scottish Beet Sugar Corporation, sliced its first beet m October of that year, and in the first three months of working extracted more than 7000 tons of white sugar from 53,233 tons of beet. After thorough washing, the beets are weighed, so that the quantity of raw material being dealt with during a given period can be ascertained if desired. The roots are then sliced preparatory to the extraction process, which is carried out by a modern method known as continuous diffusion.' The general principle of this method is the extraction of the sugar and other soluble substances by osmosis, the beet slices being made to pass in an opposite direction to a stream of water. exhausted pulp forms good stock food and is known as 'dried beet pulp. The extracted juice is then subjected to successive treatments of slaked line, carbonic acid gas, and sulphur dioxide, by which means impurities are precipitated and the liquor clarified. Evaporation, however, is necessary before crystallisation can be carried out, as the juice still contains a large quantity of water. The size of the crystals desired, which depends on the demands of the market, can be determined by conditions of temperature, vacuum, etc., during the boiling process When the mass of sugar and syrup has reached the appropriate stage it is centrifuged, whereby the crystals are retained and the syrup run off, the latter being reintroduced to the process as desired. The white sugar is dried by hot, followed by cold air, and after the lumps have been removed for remelting by 'shakers,' the finished granulated product is deposited in the sugar bins. At no time from start to finish is there any interruption in the process, nor is the product at any stage touched by hand. For the year 1927-28 more than 11,000 acres of beet are under cultivation for the Poppleton factory, and there is every prospect in this area that both the tonnage per acre and sugar content will show a marked improvement on the results of the previous year.

MAGNETIC OBSERVATIONS IN FRANCE.—The observations made at the two French magnetic observatories, Val Joyeux and Nantes, are now published under the auspices of the Institute of Physics of the Globe (of the University of Paris). Tome 5 of the Annales, recently issued, contains the results for 1925. including complete hourly values for Val Joyeux, and four hourly values per day for Nantes; the Val Joyeux records for nine disturbed days are reproduced graphic-Magnetic survey observations made in various parts of France are included in the volume, and also arctic magnetic and electric observations made on board the vessel Pourquoi Pas ? in 1926. The Director, Prof. Maurain, contributes three interesting discussions of the now long series of magnetic records at Val Joyeux and Parc St. Maur, relative to their correlations with sunspottedness, and to their annual variations. The seismological, meteorological, and actinometric observations at Parc St. Maur are also given, in summary.

MILD STEEL UNDER PROLONGED STRESS AT 300° C. -W. Rosenham and D. Hanson, in connexion with a study of intercrystalline cracking in boiler plates, have carried out prolonged tests of mild steel under loads ranging from one-third to two-thirds of the normal tensile strength of the metal at a temperature of 300° C. The results are given in a paper read at the Glasgow meeting of the Iron and Steel Institute. The loads have been maintained almost uninterruptedly for more than five years. The material used contained 011 per cent. carbon and 0.4 per cent. manganese, the other elements present being very low. Test-pieces in several different conditions of heat treatment were employed, and at stresses up to two-thirds of the normal maximum stress at that temperature, no case of fracture was observed. In one case only was there any appreciable extension. A sample coated with solder behaved in the same manner as the remainder of the specimens Brinell hardness of the steel increased to a marked extent in the stressed portions of the test-pieces, a result which is regarded as being remarkable in view of the small amount of deformation which the steel underwent. In connexion with the failure of boilers, the results are of value in proving that stress alone at the high temperatures does not lead to the type of fracture which is observed, and confirm, therefore, the view that both stress and chemical attack are necessary to produce the cracking. It is pointed out that the results were obtained on specimens free from notches, and for the present can with certainty be applied to such material only.

The Element 'Mosandrum' of J. Lawrence Smith.—In the issue of the Journal of the Washington Academy of Sciences for Sept. 19, R. C. Wells discusses the discovery of samarium, gadolinium, and europium. In 1877, J. Lawrence Smith, who was working on earths obtained from samarksite, claimed to have found a new element which he called mosandrum. About this time various chemists, including Delafontaine, Soret, and Marignac, were claiming to be discoverers of new elements, and Smith's claims received little support. Samarium was definitely isolated nine years later as a result of the spectroscopic work of Lecoq de Boisbaudran. Although it must be admitted that Smith's preparations were impure, he recognised the presence of a new element in samarksite. His element mosandrum later proved to be at least two elements, afterwards called samarium and gadolinium.

ACTIVE NITROGEN AND THE METALS.—The September issue of the Journal of the Chemical Society contains an account by E. J. B. Willey of the catalytic effect of certain metals in accelerating the decay of active nitrogen. It is suggested that clean cold metals generally have no effect upon the afterglow owing to the formation of a protective film of nitride. The active gas was passed at measured rates over a metal filament which served both as a resistance thermometer and a heating coil. An increase in temperature was observed with various metals due to the endothermic decay of the active nitrogen, but the greatest effect was obtained when a platinum filament thinly coated with copper was used. In this case 'spattering' of the copper took place, but this disintegration did not occur with other metals. It was found that iron, platinum, and silver become active catalysts for the destruction of the afterglow at the temperature of decomposition of their nitrides. The approximate value 46,600 cal./gm.mol. was obtained for the energy of active nitrogen.

THE ACTION OF LIGHT ON CHLORINE.—An interesting contribution to the photochemistry of chlorine is found in a recent paper by G. B. Kıstıakowsky in the Journal of the American Society for September. After briefly reviewing the literature on the nature of the primary action of light on chlorine, the author points out that all the existing theories which assume the presence of foreign molecules to be essential for the initial photochemical process also assume that pure chlorine fluoresces on exposure to light. It is shown that there is no appreciable difference in the total absorption of polychromatic light by very dry and by moist chlorine. Moreover, there is no change in the absorption spectrum upon extreme drying of the gas, and only a small fraction of the absorbed light energy can be re-emitted as fluorescence even in very dry chlorine. Hence, since the Budde effect undoubtedly decreases on drying chlorine, the introduction of the same amount of light energy may or may not cause a heating effect according as impurities are present or absent It is rather difficult to reconcile the new data with those theories that assume that the presence of foreign molecules is necessary for the primary photochemical process in chlorine. It is suggested that the gas is dissociated into atoms on the absorption of light independently of its degree of purity. The recombination of atoms to molecules liberates the absorbed energy as heat, but in the dry state this process must be assumed to be very slow and to take place only on the dry walls of the containing vessel, the large heat capacity and relatively good conductivity of which prevent the Budde effect. A difficulty arises in this explanation in that if moisture has a catalytic effect on the recombination of atoms, it should also accelerate the thermal dissociation of chlorine molecules.

STRUCTURES IN SEA WATER.—The committee of the Institution of Civil Engineers which has been studying the deterioration of structures of timber. metal, and concrete in sea water has recently issued a seventh report of an interin character (London: H M. Stationery Office. 2s.). Specimens of iron and steel have now been kept under observation in several parts of the world, but it is difficult to sum up the results in any simple way, as the relative behaviour of different steels varies in different harbours. Highly alloyed steels seem to have some advantage. A set of 330 mild steel plates, coated with various protective paints and coverings, has been exposed in Southampton Docks, and after a year there are marked differences in the extent of wasting and pitting, but again it is difficult to express a general conclusion. In regard to the protection of timber against the attacks of Teredo, the effect of various arsenical compounds has been examined. The protection depends largely on the extent to which the poison enters the wood, and Prof. Barger reports that a 'mixed oil,' containing 60 per cent. of phenyl arsenious oxide together with chloride, penetrates best. Limnoria is more resistant to poisons than Teredo. The organic arsenical compounds are evidently of great value in this connexion. Creosoting of timber by a low temperature process, the excess of creosote being extracted, has little effect on the mechanical strength, but the high temperature process has a deleterious effect, probably increased by the excess left in the wood. Investigations on the deterioration of marine piling are also being carried out in the United States, and an abstract of the report to the American Railway Engineering Association has been included. It appears that Australian turpentine wood has a high natural resistance to attack by borers.

# The Salisbury Meeting of the South African Association for the Advancement of Science.

THE twenty-fifth annual meeting of the South African Association for the Advancement of Science was held at Salisbury, Southern Rhodesia, on June 29-July 4, under the presidency of Prof H B. Fantham. The meeting was very well attended and ninety-three papers were read. Joint meetings of several sections were held The South Africa medal and grant were presented to Dr. Annie Porter at the conclusion of the presidential address. A popular lecture was given by Dr. A. L. du Toit on "The Kalahari and some of its Problems." There was a reception by His Excellency the Governor of Southern Rhodesia at Government House, and visits to various places of scientific interest in the neighbourhood.

The president, Dr. H. B. Fantham, gave as his address, "Some Thoughts on Biology and the Race" Dr. Fantham stated that it is to be regretted that the study of the general applications of science to everyday life are still so little evident in the education of the average citizen of South Africa He is whole-heartedly in favour of the retention of classical and cultural subjects in the high school curriculum in South Africa, but every pupil should also become acquainted with both physical and biological science during his school career. Educa-tion is not a failure, but 'what passes for it' is at fault, such as the undue desire of parents and pupils for the mere passing of examinations: in other words, the informative function has overwhelmed the truly educative function. It tends to be overlooked that all men are not born equal in inherent capacity, that is, that variation exists. Consequently, the ideal of a university as a home for culture and the training of real leaders is being supplanted by mere utilitarianism. In South Africa matriculation has become a fetish and hence a disappointment.

There is much to be said for the correctness of the aphorism that the white race must form an aristocracy of labour in Southern Africa, but it is doubtful if the idea is being fulfilled practically. Vocational training is necessary, but must not be entirely divorced from culture and must not be undertaken too early. Psychology and education must be founded on biology. Even civilisation itself must depend on the principles of biology for its constitution. One of the saddest features of the modern educational system in South Africa is that the best types of students are not desirous of entering the teaching profession. One great value of biological training is the appreciation of cause and effect and the application of these to everyday affairs. Such implies personal effort or striving, personal observation, personal thinking. To-day, however, the mass of the people seem to be merely absorptive, and adopt the views of the press or pulpit or party politician. The ideas of life as seen in the cinema, catchwords, phrases, and slogans are much to the fore. Minorities often represent the variations most fitted to survive. Many parents do not realise that they are delegating most of their parental responsibilities as regards education to the government and to the teachers

A knowledge of biology would inculcate in the parents, the presence of natural variation among children and would indicate that full opportunities should be afforded to all children for development and progress so far as their inborn or hereditary qualities allowed. If such an elementary knowledge of biology were in possession of the masses, there would be less false pride, fewer occupational misfits, more skilled craftsmen, and a truer appreciation of the dignity of manual labour. At present we are told

that we must be up-to-date and not 'old-fashioned'; in education we are told 'to follow the child' in spite of the fact that the young are immature learners. Surely a continuity should be preserved with the past and its heritages. The unfortunate disharmony that so often occurs in thought between succeeding generations is a real danger to civilisation and merely leads to repetition of old blunders. Discipline, which is such an irksome term to some modern people, only means ordered activity as opposed to disorder and chaos. A study and knowledge of biology will inculcate this discipline as perhaps no other subject can do.

Turning to another aspect, it may be remarked that probably the great cost of social services to modern white communities has been accepted by most people as a necessary expense. In South Africa, however, the financial burden is too great for the white race to carry Over-administration is a soulless, bad master biologically and has led to reaction on the part of the organisms over-administered, producing a state of lethargy and apathy (as shown by individuals not voting at elections) or else a state of violent re-action manifested by Communistic activities. Turning to the eugenic aspect, the subject of differential fertility is most important. At present, many excellent hereditary strains are in danger of being lost or are actually being lost, while the thoughtless and irresponsible are relatively increasing in numbers. As regards the colour problem in South Africa, it should be kept in mind that the real aim should be to make the native African a happier and more capable African, and not a caricature or imitation white man. At present there is not enough incentive to real effort on the part of the whites.

Biological training should be begun in early life and should receive special attention in the high schools. Biology has done much for the economic life of the people already, and more can be done. By the study of biology, humanity should be brought into harmony with the great world of Nature and carried above the smallnesses of parochial outlook and party politics. In attempting the improvement of the human race, even to a small degree, co-operation and goodwill are necessary, and by calm, dispassionate biological consideration, much can be done to break down barriers of ignorance. By service and sacrifice as a people shall we attain harmony with Nature and the infinite

An account was given of "Irrigation and Water Supplies in Southern Rhodesia," by Mr. A. C. Jennings in his presidential address to Section A. Southern Rhodesia, having no seaboard, has developed from the mland plateau along the headwaters of the rivers. In regard to irrigation, he advocated the small individual scheme, for successful irrigation requires not only good land and an assured water supply, but also a population capable of using the water to the best advantage. Rhodesia lacks population at present. Practically all irrigation is carried out by Europeans, natives making very little use of water, even when easily available. Most schemes use direct flow of rivers without recourse to conservation, and the land is devoted to mixed farming. As water and land are still comparatively cheap, there has been little inducement to effect the most economical use of the water. Investigations have been begun on urrigable possibilities of many of the larger rivers, using both normal flow and flood discharges. Conservation needs more attention and should be a national concern. Potentialities for development of water power are considerable. No general artesian basin exists, but

ground water is encountered often about 60 feet deep. Irrigation machinery has been designed and built in Rhodesia and has proved superior to imported plant.

Mr. H. B. Maufe discussed "Some Problems in Rhodesian Physical Geology" in his address to Section B Incompleteness of topographical maps has rendered many lines of research work difficult. The past geological history and present topographical features of Rhodesia were detailed Southern Rhodesia has its high ground in the form of an elevated plateau running from south-west to north-east, with mountains arising from low ground around, the high level plateau having been uplifted at the end of the Phocene, when the climate became more humid and rivers gradually carved out the valleys. The old plain, only slightly eroded, was recognisable in the main watershed, iunning from south of Bulawayo to east of Salisbury. The differences in the two types of Rhodesian scenery are not due to differences in geological structure, great stretches of flat country being found where there has been but little erosion, and hill ranges and isolated kopjes where the rivers

have cut into the flanks of higher ground.

Prof. R. S. Adamson chose "Some Problems of Vegetation in South Africa" as the subject of his presidential address to Section C The problems of a survey of the botanical resources of the Empire were mentioned, these being based on ecology. In South Africa, taxonomic work is a necessity and ecology has received less attention, but vegetation study is essential. The characters of plant succession were discussed and also vegetal changes due to climate, concerning which more accurate information is desirable. Changes due to interference, by destruction particularly of the climax vegetation and reversal of succession were noted. The recognition and definition of communities as units of vegetation study were discussed and illustrated by reference to the plant communities of the Cape region, where the flora is exceedingly rich and varied, and the 'biological spectrum' was set forth. The similarity of the Cape Fynbosch communities to those of the Mediterranean coasts, California and S. W. Australian coasts, with similar climatic conditions, was noted and various hypotheses were given to account for variability of the flora. The practical advantages of the study of plant communities in grazing, farming, afforestation, or fruit culture were indicated.

"The Teaching of Zoology in South African Schools" was the subject of Dr. S. H. Skaife's presidential address to Section D. He showed statistically that in order to give every school child some training in scientific method, the nature study course, including animal life, in the primary school must be employed. In the secondary school he advocated a four years' course in general science and not premature specialisation, as too often occurs. This should include zoology, botany, physics, and chemistry. The aim should not be to train experts in any one branch, but to create and foster a scientific attitude of mind In schools, the majority of the pupils take the matriculation course, adapted to the needs of the few who proceed to the university, and the regulations for matriculation only exceptionally allow of more than one science subject being taken, and amendment of the regulations was urged. Zoology as a school subject is of great importance and high educational value and needs better development. All teachers-intraining should receive a course in general science as part of their training. More attention to zoology as the science of living things should be given.

Rev. Neville Jones, in his presidential address to Section E, made "Some Remarks on the Present Stage of Prehistoric Research in South Africa."

The abundance of archæological relics and the recognition of three Newer Stone Age industries in South Africa were noted. The Stilbaai and Smithfield industries were regarded as specific to the Union of South Africa, but the Wilton occurred throughout the subcontinent and was probably the basal industry. In Rhodesia two industries referable to the Wilton and an older cave industry exist. An extensive Wilton workshop and distributing centre was at Sawmills: the Matopo caves yielded Wilton microlithic implements. All over South Africa evidence of a race or races equivalent to the Upper Palæolithic of Europe existed. The evolution of the Bushman and the question of the origin of the San races were discussed. The probable existence of an earlier race intermediate between the older and newer stone ages, that may have contributed to the evolution of the San people, was indicated by the occurrence in caves of implements showing a technique like that of the Mousterian of the Palæarctic. Evidence of contemporancity of these stone ages is lacking. Stellenbosch industry shows much correspondence with the early stone age of Europe, and it is thought that the European makers of Chellean implements made their way to South Africa. There are great opportunities for research in South Africa.

The presidential address to Section F on "Some Observations on the Economic Position of the Native in Rhodesia" was delivered by the Hon. W. M. Leggate, who showed by concise words and figures that the rate of progress in Southern Rhodesia and the present output of that colony in both mining and agriculture are due to the employment of native labour under European direction. The presence of a small proportion of Europeans with capital and organising ability has greatly increased the producing power of the native, who has benefited greatly in agriculture and stockfarming. In mining, the presence of the native has made it possible to work grades of ore that would be impossible if white labour only were used. Without the native, double the present white population would not maintain its present level of production, but, without the European, native production would revert to negligible proportions. The natives object to differentiation in pay whatever their capacity as workers, and differential training of the native will have to be applied gradually in consequence.

A few remarks may be made on the work of the Sections.

In Section A the hydrographic conditions, measures against soil erosion, and the variability of rainfall in Rhodesia were discussed. Engineers were interested in experimental work on water hammer and physicists in electric charges of bacteria.

Rhodesian geological problems were prominent in Section B. The pre-Cambrian atmosphere was discussed. Fossil Widdringtonia occurring in the Knysna forests, where living Widdringtonia abound, were of interest to geologist and botanist. A joint meeting was held with Section D for an important paper on the influence of variation in the ration on the assimilation and retention of minerals in farm animals. When oil is added to the ration, the calcium balance of pigs shows progressive increase, and sodium chloride or citrate added to a cereal ration causes increased assimilation and retention of nitrogen, calcium, and phosphorus.

In Section C there were valuable papers dealing with forestry, ecology and bacteriology. The behaviour of South African tree seedlings and seeds in artificial habitats were discussed, dendrographic experiments in the Knysna forests described and accounts given of *Ekebergia capensis* and Oxytenanthera. Discussions of *Clostridium botuliumin*, contagious abortion and undulant fever were of interest to

bacteriologists, and descriptions of native cattle in Rhodesia and of new fungi appealed to agriculturists.

Many subjects of wide range were discussed in Section D. An important contribution was made on the breast-shoulder apparatus of Xenopus, Pipa, and Hymenochirus. Protozoology included papers on soil Protozoa, Herpetomonads and Bodo found in the hind gut of the snake, Homalosoma lutrix, and the biological reactions of a Herpetomonas from Lucilia sericata. The distribution of Anophelini and Glossinæ in Rhodesia was described. A series of papers dealt with the structure and evolution of the fleece of various breeds of sheep. A skin of the new Cooper's cheetah, Actnonyx rex, was exhibited by its discoverer. A joint meeting was held for a paper on South African cases of racial admixture, the colour variations, poor physique, instability of character and social inheritance of such cases being discussed. A tribute was paid to the memory of Francesco Redi at his tercentenary.

A series of papers in Section E on the social anthropology of the Bomvana, Bavenda, Mashona, and Zulu peoples was of much interest, as were discussions on the religious ideas of Rhodesian natives. Stone implements of various types from several sites were discussed, and enthusiasm was aroused by the announcement of the discovery of true burns near Grahamstown. Some large and interesting collections of copies of Bushman paintings were exhibited.

In Section F the nature of attention, the distinctions between tendency, ability, and capacity, and Descartes' second meditation interested philosophers. Papers of interest to economists dealt with the industrial revolution, Indian indentified immigration into Natal and the need for the teaching of economics in South

African schools.

The next annual meeting of the Association, under the presidency of Sir J. Carruthers Beattie, will be held at Kimberley in July 1928.

#### World Weather Records.1

THE publication by the Smithsonian Institution of a collection of long-period records of pressure, temperature, and precipitation marks an important step forward in the investigation of the relationships between weather conditions in different parts of the world. The work of Prof. Exner, Sir Gilbert Walker, and others, has shown that there is some general system underlying the at first sight irregular fluctuations of weather, and that, for example, the variations of rainfall in India can be forecast from variations of meteorological elements so far afield as South America. These relationships are being sought for by the calculation of correlation coefficients between variations of meteorological elements at many different stations, a process which requires long and trustworthy records. Hitherto it has been necessary for each worker in this field to compile his own tables from the annual and monthly meteorological reports of the various countries, but at the International Mcteorological Conference in 1923, Prof. Exner proposed that all meteorological services should be asked to publish series of observations covering as long a period as possible provided homogeneity was maintained, for selected stations in their areas, at distances of 500 or 1000 kilometres. This suggestion was approved by the Conference, which passed a resolution inviting the following meteorologists to give it practical effect: Dr. (Sir Gilbert) Walker for Asia, Prof. Exner for Europe, Mr Clayton for America, and Dr. Simpson for Africa, Australasia, and the Oceanic Islands Mr. Clayton afterwards delegated the collection of data for South America to Mr. R. C. Mossman.

The four collectors commenced the work immediately by writing to the directors of meteorological services all over the world requesting copies of their long records, with details as to corrections, etc., and emphasising the importance of homogeneity. The requests met with a gratifying response, and by September 1926, when the International Meteorological Committee met in Vienna, the collection of the data was approaching completion. At that meeting Mr. Clayton was able to announce that the Smithsonian Institution would undertake the publication of the data, and that an American donor, Mr. John A. Roebling, had offered to defray the cost. This generous offer was accepted, and Mr. Clayton agreed to see the tables through the press.

¹ Smithsonian Miscellaneous Collections, vol 79 World Weather Records, collected from official sources by Dr. Felix Exner, Sir Gilbert Walker, Dr. G. C. Simpson, H. Helm Clayton, Robert C Mossmann; assembled and an anged for publication by H. Helm Clayton Published under grant from John A Roebling. (Publication 2013) Pp. vi+1199. (Washington, D.C.: Smithsonian Institution, 1927.)

The results of all this team work are now before us m a volume of some 1200 octavo pages, bearing the title "World Weather Records," which forms volume 79 of the well-known Smithsonian Miscellaneous Collections. Data are included from 385 stations. ranging from Upernivik in the north to the South Orkneys in the south. Very nearly all the series cover more than twenty years, commencing before 1900 and ending in 1920, or later in the case of the American and some other stations: shorter series were included only when the situation of the station gave it outstanding importance At a moderate estimate the tables include some quarter of a million monthly and annual means or totals. The units in which the data are expressed are those in which they were supplied by the Services concerned. The hundred thousand or so of conversions which would have been necessary to secure uniformity would have involved great labour and some risk of the introduction of errors, but quite apart from this the policy adopted was undoubtedly the wisest, and one would say the only practicable one. The tables are preceded by a number of pages devoted to explanatory notes, some of which give the whole history of the station concerned—a mine of reference—and they are followed by a useful list of relative sunspot numbers from 1749 to 1925.

Finally, a word must be said about the arrangement. The three tables—pressure, temperature, and precipitation—for each station are kept together, and the stations for each continent are kept together, in alphabetical order. There is an index of all stations and countries in alphabetical order, and another in which the stations are arranged by tendegree zones of latitude, the names in each zone running from west to east; this index gives the geographical co-ordinates. Thus whether one requires a station by name, by country, or the nearest station to some particular point, reference is equally easy.

The volume fills a need long felt by meteorologists, and by the assistance which it provides for statistical research it will certainly lead to results of great practical value. It remains only to express our gratitude to all who have had a part in its production, to the directors of the various meteorological services which have supplied data, to the five meteorologists who have organised its collection, to Mr. Clayton who has had the strenuous task of assembling and arranging the matter and seeing it through the press, and last but not least to Mr. Roebling, whose generous financial assistance has placed this invaluable collection of data within our reach.

# Forestry in Trinidad and Tobago.

THE Annual Administration Report of the Forest Service of Trinidad and Tobago for 1926 contains several points of interest connected with future forest policy. The writer states that the reasons for maintaining a certain area of the Islands under forest are twofold: first, the conservation of those forests of indirect utility owing to their protective value in maintaining favourable climatic conditions such as the maintenance of rainfall, humidity, prevention of erosion, and to act as windbreaks; secondly, the management of such areas as may be necessary for the purpose of providing the Colony in perpetuity with timber, firewood, and other forest products. The first object has been already accepted as essential by the authorities As regards the second, the Conservator writes: "Although faint flutterings to this end may be discerned a real live forestry conscience, willing to face facts and, having done so, to act up to them, has yet to be awakened." Yet these facts, as stated in the report, appear to be sufficiently obvious under existing world conditions.

In recent years the annual consumption of wood in Trinidad and Tobago amounts to more than 2,000,000 cubic feet from Crown lands, nearly 1,000,000 cubic feet of sawn timber imported from the United States and Canada, and a considerable quantity (statistics unavailable) from private lands—the annual per capita consumption being more than 100 board feet. In tropical regions the timbers are classified into soft woods and hard woods, both being broad-leaved species of trees. Trınıdad possesses excellent soft woods, such as Cedrela mexicana, Carapa guianensis, Cordia alliodora, etc., but they occur, as is usual, m mixed forests and not in pure stands. Their utilisation in the past has been affected by unlimited supplies of cheap imported comferous soft woods from the United States and Canada; consequently, as in other tropical countries, doubt has been cast on the suitability of the local soft woods for general purposes. The experiments undertaken by the Forest Department on seasoning local timbers have shown that this belief is mainly due to the lack of proper seasoning and grading methods, the Conservator pointing out that unseasoned pine timber would be equally unsuitable. Owing to the rise in price of the imported material, large and increasing amounts of local soft woods are used every year. Of the two million cubic feet of local timber used annually, possibly a fourth is soft wood, the Colony's consumption of the latter

material being therefore about 1½ million cubic feet annually. After discussing the threatened diminution in the world's supplies of soft wood coniferous timber, the writer points out that the price will certainly rise and that the Colony will be forced to depend upon its own supplies of soft woods to an increasing extent. To replace this drain on the forests, he advocates a large re-afforestation or planting campaign, suggesting that the annual surplus from the forests, which amounted to £7000 m 1926, should be devoted to this purpose.

As regards the hard woods, it appears that the Colony is well supplied and that some of them may be utilised to replace soft woods when the articles to be manufactured can be turned out by machinery. Balata (Mimusops) and pour (Tecoma) are the favourite hard woods, but mora (Dimor phandra) has been successfully used for flooring, after seasoning, by the Government engineers. The Colony, it is remarked, has always been self-supporting in hard woods. In connexion with cedar, it is of interest to note that 19,632 cubic feet cedar logs, valued at £3085, were exported, chiefly to Germany and Holland, during the year, for the manufacture of eigar boxes.

The accounts of the work in progress in the Colony, including research, amply prove that the Forest Department is devoting itself to the conservancy and care of the forests. It must, therefore, be all the more disheartening to the Conservator to find his administration crippled by the want of the necessary staff. He has two deputy Conservators in charge of the north and south of the island. He had applied for a third to act as his assistant at headquarters whilst he was on tour This post has been refused. The report shows that there are only 1000 acres of plantations in the Colony, and recommends, for perfectly sound reasons, the afforestation of 40,000 As the writer well states: "The acres by 1970 Forest Department can only point out facts." He details the facts, and in support of his suggestions quotes from the report of the recent Imperial Conference (on the subject of forest policy): "It points to the need of all countries maintaining and extending, where possible, their existing forest areas under a system of management based on sustained production of timber." The report would appear to have made out a strong case for such action being taken by the authorities of Trinidad and Tobago.

#### Gaseous Combustion.1

I. FINCH AND L. G. COWEN.—Gaseous combustion in electric discharges. Part II Ignition of electrolytic gas has been studied under different conditions of pressure and current. Ignition occurs immediately, i.e. without lag, on attainment of the igniting current, and a hyperbolic relationship exists between pressure and igniting current. Excess or deficiency of water vapour raises the value of the igniting current Flame is propagated at least ten times more rapidly along the path of the discharge than elsewhere. It is concluded that ignition is determined by the concentration of suitable ions, in the building up of which water vapour plays a rôle, and that flame propagation is also essentially an electrical phenomenon.

D. T. A. TOWNEND.—Gaseous combustion at high pressures. Part VIII. The explosion of methane with up to its own volume of oxygen at initial pressures up to 150 atmospheres. A study has been made of the

<sup>1</sup> Substance of papers before the Royal Society on Nov. 10

composition varying from 5:1 to 1:1, and (Series 2) a 1:1 mixture with  $3\cdot76R$ , where R is nitrogen, argon, or helium. In Series 1, increasing the initial pressure (a) raises the upper limit of explosibility, and (b) in the case of mixtures containing upwards of 60 per cent. of methane, not only increases the violence of the explosion, but also diminishes and in some cases suppresses altogether, carbon deposition.

explosion of (Series 1) methane-oxygen mixtures of

In Series 2, ntrogen appears to behave normally as a diluent only. The influence of helium as compared with argon is to shorten the time taken for the attainment of maximum pressure as well as to increase the subsequent rate of cooling. The corrected  $P_m/P_1$  ratios, however, were always greater in the case of explosions of the argon diluted mixture. The results accord well with the hydroxylation theory of hydro-

carbon combustion.

No. 3029, Vol. 1201

1.4.1

ments on explosions in gaseous mixtures of acetylene, of hydrogen and of pentane. Measurements are given of velocities and positions of detonation of acetylene, of pentane, and of hydrogen mixtures with oxygen, nitrogen, and argon at initial pressures up to 6 atmos. in a steel tube 15 cm in diameter. Experi-

ments in a bomb of comparatively large diameter give some evidence of auto-ignition during the progress of combustion of a vibratory character in certain acetylene mixtures. Lead tetraethyl delays the rate of combustion of the pentane in mixtures of acetylene and of pentane.

# Photosynthesis.1

E. C. C. BALY, J B. DAVIES, M. R. JOHNSON, AND H SHANASSY—The photosynthesis of naturally occurring compounds. I. The action of ultra-violet light on carbonic acid. When an aqueous allements of the product of the produ carbonic acid in quartz tubes is exposed to ultra-violet light, a photostationary state is established. Ordinary formaldehyde is not a component of this equilibrium, but there is present an organic compound which is probably a complex aldehyde. Ferrous bicarbonate in aqueous solution is converted by ultra-violet light in the absence of oxygen into ferric hydroxide, organic compounds with reducing properties being simultaneously formed. This reaction appears to take place mainly on the surface of the quartz tubes in which the solution is exposed to the light, and also on the surface of the iron rods used When an insoluble powder, capable of adsorbing carbonic acid on its surface, such as aluminium powder, barium sulphate, freshly precipitated aluminium hydroxide, or the basic carbonates of aluminium, magnesium, and zinc is suspended in water through which is maintained a stream of carbon dioxide, and the whole is exposed to ultra-violet light, complex organic compounds are photosynthesised. These may be recovered by evaporation of the solution after removal of the insoluble powder The total quantity of organic compound produced is about 0 02 gm. in two hours when eight quartz test tubes,  $9 \text{ m.} \times 1 \text{ m}$ , containing in all 720 c c. of water and the suspended powder, are exposed to the light from a 220-volt U-shaped lamp at an average distance of 6 cm. The organic compounds thus produced would seem to be of the nature of complex carbohydrates. In the presence of ammonium bicarbonate complex organic compounds are produced which contain nitrogen. Photosynthesis of complex organic material containing nitrogen also takes place when nitrite of potassium or barium is present.

E. C. C. Baly, W. E. Stephen, and N. R. Hood.—The photosynthesis of naturally occurring compounds. II. The photosynthesis of carbohydrates from carbonic acid by means of visible light. When carbonic acid, adsorbed on the surface of nickel or cobalt carbonate suspended in water, is exposed to visible light, photosynthesis of organic compounds takes place. The material contains a carbohydrate which reduces Benedict's solution, gives the Molisch and Rubner reactions, and forms a solid osazone and also contains

<sup>1</sup> Substance of papers before the Royal Society on Nov. 10.

one or more complex substances which are hydrolysed by acid to give substances which reduce Benedict's solution. For equal areas of the suspension exposed to the light, the yield of organic products is greater than that obtained with white powders in the light of the quartz mercury lamp. The percentage of carbohydrates in the products photosynthesised with a coloured surface in white light is greater than it is when white powders are used in ultra-violet light. If ammonium bicarbonate solution containing nickel or cobalt carbonate in suspension is exposed to visible light complex nitrogen compounds are photosynthesised. The shift in the exciting wave-length from the ultra-violet characteristic of carbonic acid in solution to the visible region characteristic of natural photosynthesis has been achieved in the laboratory. The photosynthesis by means of visible light has the advantage in that the photochemical decomposition of the products is avoided. Further, the special difficulties connected with the use of quartz apparatus with ultra-violet light are removed. The oxygen set free during the photosynthesis tends to poison the

surface, which slowly recovers itself under water.

E C C BALY AND J. B. DAVIES.—The photosynthesis of naturally occurring compounds.—III. Photosynthesis in vivo and in vitro. A marked similarity exists between photosynthesis in vivo and that achieved in vitro The following features appear to be common to both. Ordinary formaldehyde does not take part in the reaction in either case. laboratory process has been realised by the action of light on carbonic acid adsorbed on a surface. A limiting surface seems to exist in the chloroplast visibly coloured surface and visible light function in each process. Marked fatigue effects are observed and there is a slow recovery reaction. It appears that m both cases the photosynthesis must not proceed at a more rapid rate than that recovery reaction. It seems possible that the constant ratio of chlorophyll A to chlorophyll B in the living leaf is maintained by the carotin, which becomes oxidised to xanthophyll; the ratio of xanthophyll to carotin tends to increase during photosynthesis, so the slow recovery process may be due to the reduction of xanthophyll to carotin again. The orientation of the chloroplasts with respect to the direction of the light rays seems to be one of the details of this mechanism controlling the rate of photosynthesis.

## Surface Reactions.<sup>1</sup>

M. Francis and F. P. Burt.—Sorption of ammonia by glass. The quantities of ammonia taken up by a known surface of glass under constant temperature and pressure conditions, and the rates of sorption, have been measured over a temperature range of 0° to 200° C. and a pressure range of 100 mm. to one atmosphere. The experimental attainment of equilibrium proved impossible, but limiting values were assessed by a process of extrapolation. Though complete desiccation of glass is impracticable, it is possible to maintain it indefinitely in such a condition that its behaviour towards ammonia can be closely

<sup>1</sup> Substance of papers before the Royal Society on Nov. 10.

recovered The shape of the sorption curve depends on the dryness of the sorbent. The sorption process can be divided into two parts represented by straight lines when log sorption rate is plotted against log time. The slope of both lines is independent of pressure and varies only slightly with temperature, and their point of intersection corresponds, in all cases, to 50 per cent. sorption. By a suitable choice of co-ordinates the complete sorption process can be represented as a single-valued continuous function of temperature, pressure, and time. As regards temperature variation, this is only approximately true. At 50 per cent. sorption, the rate of sorption is nearly

proportional to the pressure at constant temperature, and is doubled for every 20° C. rise in temperature at constant pressure. At constant temperature, log sorption, in the limit, was found to be a linear function of log pressure between 0.5 and 1 atmosphere. At lower pressures a departure from linearity was observed. At constant pressure, sorption, in the limit, was found to be inversely proportional to the

absolute temperature.

G. I. FINCH AND J. C. STIMSON.—The electrical condition of hot surfaces during the adsorption of gases Part I Gold and silver surfaces at temperatures up to  $850^\circ$  C. A gold or silver surface becomes charged when heated either in contact with a gas or m a high vacuum. The charge is characteristic of the gas and dependent on the temperature and previous history of heating of the metal, but independent of the gas pressure. Evacuation of a gas removes the corresponding charge slowly in the case of oxygen or air on gold, and oxygen, air, or hydrogen on silver; but rapidly in the case of all other gases examined. The value of the charge due to a mixture of two gases, whether reacting with each other or not, is intermediate between the charges of the component gases and, as a rule, identical with that due to the reaction product. It is concluded that the charging of the surface is due to 'activation' of the gas, whereby the gas molecules are electrically charged. With oxygen, some become positively charged and remains thus charged on the surface, and some becomes either positively charged and quits the surface in this condition, or is negatively charged and remains on the surface. Gases other than compounds of oxygen are, on 'activation,' either positively charged and quit the surface in this condition, or are negatively charged and remain on the surface Oxygen forms an oxide with gold or silver, and hydrogen a hydride with silver. The 'activating' powers of the surface are greater towards oxygen than towards nitrogen or carbonic oxide, but very approximately the same towards oxygen and hydrogen. The 'activation' of water vapour or earbon dioxide involves at least dissociation of the gas. Vapour of the metal is activated in the process of leaving the surface.

D. R. HUGHES AND R. C. BEVAN.—A study of the catalysis by mckel of the union of hydrogen and oxygen by a new method. When hydrogen and oxygen at a low pressure are caused to combine at the surface of a nickel wire heated electrically, there is no alteration in the appearance of the wire, although the wire is covered completely with a very thin film of nuckel oxide while the catalysis of the reaction is in progress. The extent of the surface covered by the film can be measured by estimating the heat lost by the wire when it is maintained at a fixed temperature in hydrogen at a low pressure Under the same conditions the heat imparted to the hydrogen by a wire covered with a film is much greater than that communicated to the gas by a wire having a metal surface. The thickness of the films varies between  $3\times10^{-7}$  cm. and  $9\times10^{-7}$  cm. It is therefore incorrect to speak of the catalysis of the interaction of hydrogen and oxygen by the metal nickel.

B Lambert and A. M. Clark.—Studies of gas—solid equilibria Part I Pressure—temperature equilibria have been measured over a range 30° to 130° C. for (a) ten systems containing different amounts of benzene and ferric oxide gel; (b) eight smilar systems containing different amounts of benzene and silica gel. Pressure—concentration isothermals for benzene—ferric oxide gel systems and for benzene—silica gel systems are strikingly different in shape for these two closely analogous systems. The adsorptive processes of the two gels for condensible vapours are thus profoundly different, and doubt is cast on Zeigmondy's capillary theory as a general explanation for adsorption of condensible

vapours by inelastic gels.

# The Neanderthal Phase of Man.

N Tuesday, Nov. 8, the Huxley Memorial Lecture of the Royal Anthropological Institute was delivered in the lecture room of the Royal Society by Dr. Aleš Hrdlička, Curator of the Department of Physical Anthropology, U.S. National Museum, Washington, who took as his subject "The Neanderthal Phase in Man." For science, the subject of human evolution has long since passed from the realm of theory or hypothesis into that of well-substantiated facts. Many important details, however, of this most wonderful and promising of natural phenomena remain to be determined or settled. One of the foremost of these is the question of the Neanderthal stage of humanity, corresponding roughly to about the fourth fifth of the glacial time. From Huxley and Lyell to Sir Arthur Keith, Elliot Smith, Sollas, Marett, Burkitt, and Karl Pearson, all the noted English, besides a host of Continental and even American anthropologists, have given this stage of human prehistory their earnest attention, without being able to reach final conclusions. The chief cause of this has been the dearth of the skeletal remains of Neanderthal man. Even with repeated finds, material in good condition was insufficient for what is needed.

Notwithstanding this, the indications appeared to justify certain views, and these, formulated by men of high authority, were soon generally accepted. The chief of these was the opinion, fathered by the noted German anthropologist Schwalbe, that Neanderthal man was radically different from later man; that during or soon after the last maximum glaciation he was suddenly and completely displaced by a new

human species, *Homo supicus*, who came from some where outside, from the south or, more likely, from the east; and that he left no progeny

As time advances, however, ever more remains of

Neanderthal man come to light, and as the subject is studied more thoroughly, it appears that this older view is in need of a substantial revision. It is now known that no marked disturbance in habits (housing, food, etc.) between Neanderthal and later man can be determined. Neanderthal man occupied a great territory, comprising the larger part of Europe with northern Africa (at least) and western Asia, and nowhere is the higher type of man found to precede him or to live contemporaneously. Abruptly or even slowly to annihilate such an extensive population as that of the Neanderthalers would seem impossible. No separate home of Homo sapiens has been discovered; he does not appear with a higher culture. but gradually develops the latter. As his Neanderthal predecessor he knows fire, but no agriculture, no domestication of animals, not even a dog or a cat, makes no pottery, nor even the crudest of walls, and remains for a long time yet in the palacolithic stage of the stone industry Beyond which, the more the remains from the Neanderthal and the succeeding periods grow in number, the more there appear of transitional features; and this applies to both the archæological as well as the skeletal remains. is a growing series of Neanderthal skulls, and jaws that distinctly approach those of later man (i.e. Spy No. 2, Weimar, Gibraltar boy, etc.), and, on the other

hand, an ever-increasing number of later crania and

laws that approach the Neanderthal forms. Moreover, it is biologically certain that man in the course of his evolution must, at some time and somewhere, have passed through a more or less Neanderthal-like stage.

In view of all this, it appears progressively less safe to persist in regarding Neanderthal man as a separate species of man, and to close the door to the possibility of further human evolution from his midst. The indications are that before long science will be in a position to view the Neanderthal man and his culture as regular and inherent phases of human evolution

At the end of the lecture, the president of the Royal Anthropological Institute, Mr H J E. Peake, presented the Huxley Memorial Medal to Dr Hrdlička.

# University and Educational Intelligence.

CAMBRIDGE — Dr. P. M. Dirac has been elected to a fellowship at St. John's College. Mr. McLean, master of Christ's College, has been elected a member of the Council of the Senate.

Regulations have been proposed to the University for the newly founded Rouse Ball professorship of mathematics. It is not proposed to assign the new chair permanently to any one branch of mathematics, but if the General Board so decides at any election, it will be specified in the notice to candidates that preference will be given to those whose work is connected with some particular branch or branches of mathematics.

R. O. Redman, St. John's College, has been elected to an Isaac Newton studentship; J. A Gaunt, Trinity College, and S. Goldstein, St. John's College, have been elected to additional Isaac Newton studentships for one year.

The President of the Board of Education has appointed a Departmental Committee to inquire into the public system of education in Wales and Monmouthshire, in relation to the needs of rural areas, and to advise how those needs may best be met, having regard to the requirements (1) of a general education, (2) of rural industries, businesses, and professions; and (3) of life in a rural community. Sir John Eldon Bankes is chairman, and Mr. C. P. Clayton, Assistant Inspector, Welsh Department, Board of Education, is secretary to the Committee. All communications should be addressed to the secretary.

The Institution of Naval Architects is offering the Elgar Scholarship (£130 per annum) and the John Samuel White Scholarship (£100 per annum) in naval architecture for competition in 1928. These scholarships are tenable at the universities of Glasgow (four years), Durham (Armstrong College) and Liverpool (three years), and the Royal Naval College, Greenwich (three years) They are open to British apprentices or students who have not yet entered upon a university course Full particulars may be obtained from the Secretary, Institution of Naval Architects, 5 Adelphi Terrace, London, W C.2.

The calendar for 1927–28 of University College, London, now entering upon its one-hundredth session. is of exceptional interest, containing, as it does, a full record of the proceedings of the centenary celebrations. The College is remarkable alike for the range

of its work and for the unusually ample provision for advanced study and research. Of the 800 pages of the calendar a large number relate to post-graduation study, particulars being given of courses of advanced lectures in forty-three departments, including a series arranged by Prof. Wolf, with the co-operation of other professors and teachers of the University, on the history, principles, and methods of the sciences. There is a list of some 450 original papers published during the past twelve months in 37 departments, notably anatomy (52), physiology (53), chemistry (45), and history (45). The number of graduate and research students last year was 534.

-10 U'L

'INDUSTRIAL Administration' has been a subject of university study in Great Britain since 1918, when a group of business men promoted and largely financed a department in the Manchester Municipal College of Technology. In the prospectus of the College for 1927-28, particulars are given of a one-year post-graduate course covering the following ground: industrial output, purchasing and stock-control, economic history, history of industrial organisation, factory law, wage systems and factory costing, business statistics, industrial relationships. The Director of the Department, Dr. J. A. Bowie, in a recent address to a managers' association, defined his subject as the technique and problems of industrial management with special reference to the internal organisation of manufacturing concerns. The two great faults of British management to-day, he said, are secretiveness and an unwillingness to learn, and the remedy is to be found in requiring managers to study management before they attempt to practise it. He quoted Mr Hoover as having said that the enormous industrial progress of the United States is due mainly to the emphasis placed there on business education, and remarked that about a hundred American universities and colleges have schools or departments of business administration.

AT the League of Nations Assembly in September a report was presented on the work of the League's Committee on Intellectual Co-operation. The report directs special attention to the creation at the International Institute of Intellectual Co-operation of a co-ordination service of information offices attached to libraries, to the Committee's proposals for co-ordination between the organs of bibliography for the various sciences, to the need of funds for the maintenance of the Office for Annual Tables of Constants and Mathematical Quantities, and to the steps taken in preparation for the Popular Arts Congress (to be held at Prague in 1928), for an international agreement with regard to casts, and for promoting the extension of the educational work of museums It is also pointed out that additional funds are needed for the Institute, grants to which are at present made only by the following countries: Austria, Czechoslovakia, France, Hungary, Italy, Monaco, Poland, and Switzerland. The question how to protect and reward men of science and their discoveries by means of an international convention has been investigated during the past five years, and it is now thought that the matter is ripe for definite action. It is intended therefore to convene a committee of experts to prepare a draft convention. A separate report was submitted on the Italian proposal for the creation of an educational kinematographic This proposal looks to the creation at institute Rome of an institute under the direction of the League of Nations, but to be carried on at the expense of the Italian government.

# Calendar of Discovery and Invention.

November 20, 1817.—It was in 1743 that the Government first offered a reward for the discovery of a North-West Passage, and several attempts were made in the eighteenth century to find a passage. The resumption of such expeditions after the Napoleonic wars was largely due to the Royal Society, Sir Joseph Banks writing on Nov. 20, 1817, to Lord Melville "that discoveries may now be made . . not only interesting to the advancement of science, but also to the future intercourse of mankind and the commerce of distant nations." The outcome of the suggestion was the fitting out of the Isabella, Alexander, Dorothea, and Trent, respectively, under the command of Ross, Parry, Buchan, and Franklin

November 21, 1843.—Of the invention of vulcanised rubber patented by Thomas Hancock on Nov. 21, 1843, the inventor left a most interesting account in his "Personal narrative . . . of the India Rubber manufacture in England" (1857). Some time in 1842 his friend Brockedon gave Hancock some bits of rubber received from America which did not stiffen with cold. In his private laboratory at Stoke Newington, Hancock, groping "a good deal in the dark," ultimately discovered the changes brought about by mixing rubber and sulphur at various temperatures. Setting out to manufacture the new material on a large scale, he sought for a name, and it was Brockedon who suggested the term "Vulcanisation," which "owes its derivation to the Vulcan of mythology, as in some degree representing the employment of sulphur and heat, with which that mythological personage was supposed to be familiar."

November 22, 1675.—The first determination of the velocity of light was made by the Danish astronomer, Roemer, who, while engaged under Picard in Paris, studied the motion of Jupiter's satellites, and by observing their immersions and emersions found that light took about sixteen minutes to travel a distance equal to the diameter of the earth's orbit. This important result was communicated by him to the Paris Academy of Sciences on Nov. 22, 1675, and gained for him a seat in the Academy.

November 23, 1889.—In a letter to her daughter, dated Nov. 23, 1889, Mrs. King, the meee of Lord Kelvin, refers to Lord Kelvin's "meeting with the Admiralty, which was most satisfactory, for it is now ordained that his be the standard compass and be used throughout the Navy." There had, however, been attempts to prevent the adoption of the compass, approving letters having been pigeonholed. "I believe," says Mrs. King, "this had been going on for years, and that Admiral Fisher has been instrumental in exposing the abuse. . . There is much of the circumlocution office in the whole affair. Uncle William does not want it talked of . . ."

November 24, 1831.—In the course of ten days' work, spread over the months August to November, 1831, Faraday made his memorable discoveries in induced currents and magneto-electric induction. In his experiments he employed among other apparatus the famous iron ring, and the copper disc revolving between the poles of a permanent magnet now preserved in the Royal Institution. His results, amplified and extended, were presented to the Royal Society on Nov. 24, 1831. "So exhaustive was his treatment of the subject," said Prof. Fleming, "that no one has since added a single new fact or principle which is not implicitly contained in the record of this work thus given to the world."

November 26, 1725.—The discovery of the aberration of light by Bradley resulted from observations begun at Kew, Nov. 26, 1725. E. C. S.

#### Societies and Academies.

LONDON.

Royal Society, Nov. 10 —Sir Richard Paget. The origin of speech. (See Nature, July 9, p. 47.)

#### NUCLEAR PHYSICS

C. D Ellis and W A. Wooster. The average energy of disintegration of radium E. The average energy of disintegration of radium E is found by measuring the heating effect of a known amount of the material. It agrees with the mean energy of the continuous spectrum of electrons emitted from the nucleus, and the conclusion is drawn that the energy of disintegration is not a characteristic constant of a  $\beta$ -ray body but varies from atom to atom. From this result it appears that the  $\gamma$ -rays cannot be emitted by the electronic part of the nucleus but must have their

origin in the positive portion.

P. M. S. Blackett and E P. Hudson The elasticity of the collisions of alpha particles with hydrogen nuclei. Inelastic collisions involving the ejection of a proton from the nuclei of certain light elements are known to occur. They may also occur without, however, a proton being ejected; for example, the nuclei might be deformed without being disintegrated, or energy might be radiated by the rapidly accelerated This problem can be investigated directly by precise measurements of photographs of the collisions taken by the Wilson condensation method. The collisions of fast a-particles with hydrogen nuclei provide tracks which are susceptible of great accuracy of measurement and therefore would reveal any small energy loss should such occur If any loss of kinetic energy occurs it must be less (for the most favourable of the two tracks measured) than 1/200 of the initial energy of the  $\alpha$ -particle; less, therefore, than 40,000 electron volts If a quantum of radiation were emitted during the collision, its wave-length must be greater than 0.3 A.

#### SPECTRUM ANALYSIS.

E. T. S. Appleyard and H. W. B. Skinner. On the excitation of polarised light by electron impact. II.—Mercury. It has been shown that when spectrum lines are excited by a directed stream of electrons, they are variously polarised. Measurements of the polarisation by means of photographic photometry are now described. The most important feature of the curves obtained is the maximum value of the percentage polarisation which occurs when the energy of the electron stream exceeds the critical energy for excitation by a few volts. On the low-velocity side of the maximum, the polarisation falls very sharply, apparently to a zero value at the critical point. For high velocities, corresponding to 200 volts, the direction of the plane of polarisation is reversed. The results can be interpreted as a collision process in which an atom is excited by electron impact.

J. C. McLennan, H. Grayson-Smith, and W. T. Collins. Intensities in the secondary spectrum of hydrogen at various temperatures. The intensities of most of the lines measured by Merton and Barratt in the secondary spectrum of hydrogen have been measured by means of a microphotometer at two temperatures. For Richardson's series system the change of intensity with temperature is generally in good agreement with theory. The alteration of intensity between the odd and even members of the series is also clearly shown. Other regularities which have been found in the spectrum have also been examined, and from the change in intensity, many of these appear to be sequences of corresponding

members of different bands, rather than actual band series

B. Venkatesachar: Density of the vapour in the mercury arc and the relative intensities of the radiated spectral lines with special reference to the forbidden line 2270. The effect of lowering the density of the vapour on the series lines in the arc spectrum (includmg inter-combination lines) is to increase the absolute intensities of all lines below m=5 and diminish those of all lines above m=6. This result can be explained on the hypothesis that inelastic collisions between excited atoms in lower energy levels and thermally energetic normal atoms form the chief source of the radiators of the higher members of series lines. To the radiators of the lower members the contribution from this source is negligible. On increasing the vapour density, collisions between the radiators of the lower members and normal atoms resulting in radiationless transitions increase and the intensities of these lines fall – The forbidden line  $\lambda 2270$ , like the lower members of other series lines, increases in intensity when the arc passes to the low density

O. W. Richardson. On the intensity distribution among the lines of certain bands in the spectrum of the hydrogen molecule. The intensities of the lines of the Q branches of various bands of the hydrogen spectrum were examined critically, using the measurements of McLennan and his collaborators. The odd numbered lines are nearly three times as strong as the even numbered. The analysis shows that antisymmetric emitters are three times as numerous as symmetric. This holds for various vibration states of the 3-electron state and probably also for the 4 state. The ultra-violet spectrum data seem to require it to hold also for the 2 state, and Dennison's analysis of the specific heat of hydrogen requires it for the

l state

J. S. Foster · Application of quantum mechanics to the Stark effect in helium. New measurements of displacements of helium components in fields of 100,000 v./cm. and 83,000 v./cm. are recorded. The first-order displacements have been calculated at several field strengths for components of the line groups 2P - (4Q, 5Q), 2S - (4Q, 5Q) and for the corresponding orthohelium lines, considered as singlets. These displacements are in good agreement with observations at all field strengths. Approximate positions of the components at extremely high fields are calculated, and the manner in which certain components are expected to cross each other in moderate to high fields is described. In the case of two lines, at least (2P-4F, 2P-5G), there is conclusive experimental evidence of such crossing. In particular, the theory accounts satisfactorily for the observed disappearance of numerous components when the displacement is equal to that of the 2P-nP line at zero field.

R. W. Ditchburn: The continuous absorption of light in potassium vapour. The absorption found is believed to be due to a combination of molecular and atomic absorption. The results are discussed in connexion with the theory of atomic and molecular absorption; the amount of atomic absorption appears be much less than that expected. The heat of dissociation of the potassium molecule is derived from the absorption curves and used to calculate the degree of association in potassium vapour at different temperatures.

J. W Ryde: The spectrum of carbon-arcs in air at high current densities. The positive carbons were cored with metallic salts. Under suitable conditions, this allows steady arcs at high-current densities to be obtained. As the current through such arcs is in-

creased, a bright central core develops in the arc stream. In this core it was found that spectra of C I, N I, O I, together with the Balmer hydrogen lines and the strongest lines belonging to the red spectrum of argon, are excited. The relative intensities of C I and N I lines, previously only tound in special discharge tubes, are compared with those found in the arc stream. More than fifty new lines were observed. These also are probably due to either N I, O I, or C I.

#### TENSOR AND DIFFERENTIAL CALCULUS.

J L Burchnell and T W Chaundy: Commutative ordinary differential operators. Associated with any polynomial f(p,q) of a certain type is a group [P,Q] of pairs of commutative operators which also satisfy the identity f(P,Q)=0. The construction of these operators is based on the set of Abelian equations of the first kind associated with the polynomial f(p,q), the function  $\eta(p,q)$  which is annihilated by both P-p,Q-q is an Abelian function of the second kind. If P',Q' denote the operators adjoint to P,Q, then the group of adjoint pairs [P',Q'] can be derived from the group [P,Q] by change of sign of x, and in particular there is one pair in the group which can be derived from its adjoint in this way. If P,Q is a commutative pair, there are operators T such that we may write

 $\mathrm{TP} = \mathrm{P_1T}, \qquad \mathrm{TQ} = \mathrm{Q_1T},$ 

where  $P_1$ ,  $Q_1$  are other operators also commutative and obeying the same identity as P, Q

T. M. Cherry · Periodic solutions of Hamiltonian systems of differential equations. The existing theory (Pomcaré's) is unsuited to finding the mutual relations of the periodic solutions of a fourth order Hamiltonian system. Periodic solutions occur in general in continuous singly infinite families. With each solution of a family is correlated a number R which may be real or unreal and varies continuously along the family. From any solution S for which Ris real and rational there branch two (in general) new families, whose periods near S are approximately integral multiples of the period of S. A family for which R is real thus throws off branches at all its rational' members. These families, when real, are susceptible of a geometrical representation in which to each periodic solution corresponds a point, and to each family a line in 3-dimensional space. Taking the whole aggregate of such lines, they apparently join up so as to form a system of closed meshes of complicated character, only partly elucidated.

M. H. A Newman A gauge invariant tensor calculus A 'projective' differential calculus is developed, capable of dealing with tensors of various weights,' as well as tensors of various ranks. The equations preserve their form both under a change of co-ordinates and under a change of measure-system. The theory is applied to find a tensor and gauge-true form for the identities given by the variation of integrals. The general gauge-true equations resulting from the law

$$\delta \int \mathbf{R}^2 \sqrt{g} = \mathbf{O}.$$

are obtained. The part independent of the 'electrical' vector  $\phi_1$  is found to be

$$G_{ik} - \frac{1}{4}Gg_{ik}$$

a tensor which has been considered by Einstein from time to time in connexion with the theory of gravitation.

F. B. Pidduck: Adjoint differential equations · E. Bortolotti showed that adjoint differential equations have a certain analogy with sets of linear algebraical

equations in which rows and columns are interchanged in the matrix of coefficients. G. D. Bukhoff gave a rule for finding a set of adjoint boundary conditions which make the fundamental integral, or bilinear differential form, vanish when taken over the whole range. The present paper traces the appearance of the adjoint equation and boundary conditions when the number of unknowns in the linear equations tends to infinity.

(To be continued.)

Mineralogical Society, Nov. 1 (Anniversary Meeting)—L. J Spencer: (1) Specific gravities of minerals: an index of some recent determinations. Specific gravity as determined by heavy liquids affords a convenient first-aid in the determination of minerals. 2277 determined values collected from the recent mineralogical literature are arranged numerically, and an alphabetical index of mineral names gives the minimum and maximum values for each mineral.
(2) South African occurrences of willemite Fluorescence of willemite and some other zinc minerals in ultra-violet rays. Willemite is described from Broken Hill and two other localities in Northern Rhodesia where it appears to be of abundant occurrence, and from Guchab in South-West Africa. Unlike the willemite of Franklin Furnace, New Jersey, some of these not do fluoresce in ultra-violet rays. Fluorescence is not a constant and essential character of a mineral species, and it evidently depends on the presence of admixed impurities.—T. V. M. Rao. A study of bauxite. Specimens of laterite from India, Gold Coast, and other countries were described. It was shown that laterite is a rock largely composed of the mineral bauxite, which has a definite composition corresponding to the formula Al<sub>2</sub>O<sub>3</sub>, 2H<sub>2</sub>O. Details of an experiment to trace the process of laterisation in Nature were also given—P. K. Ghosh: On the biotite-bearing greenstones and on a rhyolitic pumice in the metamorphic aureole of the Falmouth grante. The biotite constituent, which has so far been ascribed to the inctamorphic action of the Armorican granite on the pre-existing greenstone, is proved to be the undigested and residual part of the slate fragments stoped by the 'greenstone' magma at the time of its intrusion. Rhyolitic pumice is noted for the first time in this region and its mineralogical characters are described.

Society of Public Analysts, Nov. 2.—Sir William Willcox: The biological tests for blood. An outline was given of the evolution of blood tests, from the days when the only differential method available was based on differences in the form and size of the blood corpuscles, down to the refined serum tests of the present time. Caution is necessary in using bought specific sera for these tests, since they were frequently mert.—G. Roche Lynch. The technique of the precipitin test and its forensic value. The various methods of preparing anti-sera, the extraction of blood stains, the filtration and sterilisation of the extract by means of special apparatus, the methods of determining the concentration of the extract, and the various ways in which the precipitin test can be applied were described.—F. C. Martley The use of the blood grouping reactions in forensic investigation. By means of the four blood groups into which the blood of different individuals can be classed, it is often possible to distinguish between the blood of different persons. The method has applications in forensic work and in determining paternity.

Arademy of Sciences, Oct. 17.—A Lacroix: First observations on the mineralogical and chemical com-

position of the Mesozoic and Tertiary lavas of eastern China. The lithological types observed melude rhyolites, dacitoides, andesites, basalts, and limburgites. All the rocks which are not basaltic are very poor in coloured minerals and they all contain free silica.—F E. Fournier The horizontal resistance of water to the translation of hulls. - d'Arsonval. The heating of tissues by high-frequency currents. A description of experiments with the 'long chair,' in which the patient and a metallic plate form the plates of a large condenser. The body of the patient was replaced by a bottle containing salt solutions of varying concentrations, and the corresponding rises of temperature measured —Ch. Riquier: The numerical resolutions of systems of integral algebraical equations with any number of unknowns.-P. Vincensini: Congruences with mean plane surface.—
E. Lainé The partial differential equations of the second order of the form s=p(x, y, z, q) which are of the first class—Stefan Kempisty. The integral (A) of M. Denjoy.—Georges Alexits—The divergence of Fourier's series of continued functions.—N. Podtiaguine: Regular increasing functions.—Antomo Cabreira: Algebraical schemes of the dates of the lunar phases and the table of relative tides.—E. M. Antoniad:: The rotation of the planet Mercury. The observations described confirm the discovery of Schiaparelli, that the period of rotation of Mercury is equal to its period of revolution -G. W. Ritchey: A type of fixed vertical photographic telescope, with cœlostat, with interchangeable focal ratios.—Léon and Eugène Bloch: Spark spectra of higher order of sulphur and selenium. The sulphur (or selenium) was enclosed in an evacuated quartz tube, without electrodes, and excited by an oscillating discharge in a solenoid wound round the tube. Tables of the lines measured are given -W. Swietoslawski and Mlle. A. Dorabialska. An adiabatic microculorimeter for radiological researches. The microcalorimeter described and illustrated has a thermal capacity so low as 0.08 calories The instrument has been used to determine the heat evolved by 4.3 milligrams of radium, the rise of temperature found being 0° 0808 per hour. It has also been possible to measure the heat given off by the  $\alpha$ - and  $\beta$ -rays of one millicurie of radon contained in a capillary tube. Vasilesco Karpen: Batteries with unalterable identical electrodes—René Audubert. The valve effect presented by a silicon anode and its mechanism. A very efficient rectifier is produced by a cell with a silicon anode. it is shown that the effects produced are connected with an oxidation-reduction process.— Mlle. C. Chamié. The existence of groupings of atoms of radioactive elements in acid solutions and in surfaces activated by the emanation.-Jean Cournot and Jean Bary: The use of electrolytic deposits of cadmium for the protection of metals and alloys against corrosion. Cadmium plating is superior to nickel plating in being non-porous and consequently shows high resisting power to corrosion. On the other hand, the deposited cadmium is not so hard as nickel and soon loses its high polish Good results were obtained by cadmium and nickel together. Ed. Chauvenet and E. Duchemin: The combinations of zirconium oxychloride with the alkaline chloride. No thermal effect, and consequently no compound could be shown by mixing solutions of zirconium oxychloride (ZrOCl<sub>2</sub>) with lithium, sodium, or potassium chlorides On the other hand, definite compounds of zirconium oxychloride were proved with ammonium chloride, rubidium chloride, and cæsium chloride.-G. Denigès: Stable and unstable molybdenum blues. Analytical applications to the detection of phosphoric and arsenic ions. Details of the preparation of a

No. 3029, Vol. 120]

reagent for the detection and estimation of minute traces of phosphates -Amand Valeur and P. Gailliot . Study of the products of high boiling-point contained in oil of Cadet A new type of arsenic compound has been isolated containing three atoms of arsenic in the molecule; these bodies are chemically very stable. L. Joleaud. Contribution to the stratigraphical study of the Tertiary soils of the Caribbean regions of South American Colombia — Léon Moret The extension of the phosphate deposits in the Haut-Atlas of Marrakech (Western Morocco) - Jacques de Lapparent · The occurrence of dolomitic walls in bauxite deposits -Ch. Jacob: The structure of the Turbon, Cotiella, and Castillo-Mayor in Haut-Aragon.—A Maige marks concerning the greening of plant cells—Mile. Suzanne Ancel The action of time and intensity in the effect of irradiation by the X-rays on germinated seeds. Under the conditions of the experiments described, and for an equal dose of X-rays, the increase of time of irradiation with diminution of intensity shows a clear and constant diminution of the effect of the rays—R Franquet The formation of aerial tubercles of the Jerusalem artichoke without grafting —L Mercier · The presence of Chrysomyia albiceps on the coast of Calvados.—A Policard. Studies in microdissection on the cartilage of growth of bones.—R Fosse and A Hieulle. A mercuric compound of allantoic acid permitting the identification of this ureide in the green legume of Phaseolus vulgaris.

## The Influence of Science on Ethics.1

N his Norman Lockyei lecture, delivered on Nov 21 under the auspices of the British Science Guild, Dean Inge discussed the effect which the advance of scientific knowledge has exercised upon our modern notions of morality and our ideals of practical conduct. It is difficult in a discussion of this sort to separate religion from ethics, for in practice they are closely intertwined, and the influence of scientific conceptions has perhaps been greater upon religious thought than upon moral tendencies. Science reveals a world incomparably vaster than was dreamed of in the days when the great religions were founded has relegated man and his works to a re- wite and obscure corner of the cosmos, rollbing him end. proud position which he arrogated to him self a to centre and crown of creation. Selence has, in a fore, profoundly modified religions and are Has it had an equal effect upor more seems to us that the effect has been mainly :. acting through the changed conceptions . cosmos which science has imposed, and Dear Ing. remarks appear in general to support this view.

Dean Inge discusses first the problem so clearly stated by Huxley in his famous Rom - Lecture Huxley considered that the ethical proc. counter to the cosmical process, that the muiai life must be a constant fight against the lower instincts and desires which man has inherited from his animal ancestors. Law and morals he considered to be necessary restraints upon the struggle for existence between men in society, and his final conclusion was that "the cosmos works through the lower nature of man, not for righteousness, but against it." Being a man of fine and strong character, and in many ways a typical Victorian, Huxley laid immense stress upon righteousnessupon honesty and courage in thought and action and the paramount claims of duty. He was over impressed by the Victorian conception of Nature as red in tooth and claw, of life as a bitter struggle in which the prizes go to the strong and ruthless The opposition which he set up between moral Victorian man in societies, and prodigal, careless, and cruel Nature, seems to us now too rigidly drawn. After all, man also, with all his finer desires and aptitudes, his creativeness in art and science and philosophy, is a part of Nature; and, on the other hand, some of the despised lower instincts which he shares with the rest of the animal

<sup>1</sup> Scientific Ethics By the Very Rev Dean Ingo (British Science Guild, 6 John Street, Adelphi, London, W C.2) 18.

world are the basis of courage and self-sacrifice in man himself as well as in the lower animals. Protection of mate and offspring and sacrifice of self on their behalf are developments of the fundamental instinct of reproduction which is as powerful in man as in the lower animals.

Dean Inge describes Huxley's position as one of radical pessimism, and he is far from sharing it He does not think that we are forced to consider the universe as radically unfriendly. The main error of the Huxleyan view was that it considered the cosmic process apart from man. To do this is to despiritualise Nature

"The cosmic process," says Dean Inge, "is responsible for man as he is, with all his unselfish devotion to family, friends, and country, and all his pity and sympathy with the weak, all his idealism and belief in the unseen, as well as for those brute-instincts, which Read thinks are too often forgotten by moralists and reformers. We

t committed to anything so hopeless as a gainst the cosmic process."

to the positive contributions which the atific spirit makes to ethics, Dean Inge finds nese mainly in the influence exerted by the increased clarity and honesty of thought which are the result of free and unbiassed inquiry into the nature of things. Thus he thinks that we may expect to see a more exacting standard of accuracy in forming and expressing opinions Signs of this influence of the scientific spirit are already to be seen even in theological controversy, where "in those churches which are affected by the scientific conscience, there is much less garbling of facts and vilification of opponents than there used to be." Science will help too in driving out superstition and the baser forms of supernaturalism. "Perhaps nothing has corrupted the Christian religion so profoundly as the unethical magic which in many different forms has pervaded it: and it all rests on this assumption that there is a 'supernatural order,' which from time to time 'suspends' the laws of Nature, breaking the natural sequence of cause and effect." True religion, sound ethics, and the spirit of science can make common cause in resisting such beliefs. So, too, though science has nothing directly to do with theology, it may do good service by showing the inadequacy and poverty of the cruder conceptions of God which have done more harm to religion and ethics than the assaults of dogmatic atheism.

An interesting question is raised by Dean Inge's clause that the proof of our blood-relationship with the other-animals supplied by the doctrine of evolution has led to a more humane treatment of

animals In countries where the Church has firmly resisted the evolutionary doctrine, animals are: a rule cruelly treated. No doubt there is truth this view, but it does not seem to us the whole truth, for there have been in all parts of the world lovers of animals and kindly masters long before evolution was dreamt of We hope, with Dean Inge, that the influence of science, and certainly of scientific men, will be exerted against the wanton destruction of plant and animal life and against the ugliness which seems inseparable from a mechanical civilisation, but we feel that the driving force must come not so much from the spirit of intellectual inquiry as from æsthetic and moral feeling

Dean Inge devoted an important part of his lecture to a consideration and advocacy of the eugenist position It is here that the direct influence of scientific thought and of the results of scientific inquiry upon conduct and practice, and even upon political action, is most fully exerted. A very definite ethical problem is raised, which gives rise to much conflict of opinion Science has shown the importance of taking long views, of providing for the future improvement of the race, and avoiding racial deterioration. Instancing the action taken by America in drastically limiting the immigration of inferior stocks, Dean Inge points out how profoundly this scientific point of view is beginning to affect practical morality and the conduct of human life. We do not propose t enter into a discussion of the eugenist case, on which there is much to be said both for and against, bu we confess to some surprise in finding Dean Ing stoutly maintaining that the new eugenic morali is more Christian than the moral traditions of t' pre-scientific age. This does not seem to us to! fully reconcilable with his own remarks quet above about man and the cosmic process, will pity and sympathy for the weak are rightly rank among the higher instructs of man.

Has the over elaborate civilisation which is to product in the main of the scientific age really to an increase of happiness or enhanced the dignit and value of the individual life? This is a important question which is dealt with in the concluding sections of the lecture. The mechanition of human life has proceeded apace. "Civilition—the accumulation of experience and of took seems to have brought intrinsic evolution to an endem of the slave is only half a man. Is there any cure for this state of things, any means by which man migh recover his lost opportunities for a full and rounded existence? And can science help towards this end?

"It seems to me," says Dean Inge, "that science 'ght to advocate a return to much simpler conons A happy and healthy country would be Ar bited—much more sparsely than England is at resent—by a population mainly agricultural, with small towns well supplied with schools, colleges, and laboratories. The passion for production at all costs would die a natural death, since the market for standardised products, now artificially stimulated by all the arts of scientific advertising, would be comparatively small. There would not be much of mere drudgery, for we should still have our labour-saving machines; but the arts and crafts would not be strangled and exterminated as they often are now The instinct of acquisitiveness has become a positive disease; it should be checked by the principle already enunciated, that no needs should be indulged beyond their biological justification. No one should be condemned to the ceaseless repetition of one simple act as his life's work, the human frame and nervous system are not adapted to such unrelieved monotony. It is the dullness and irritation of mechanical labour that drive men to alcohol, gambling, and Bolshevism."

A rational simplification, such as is here suggested, of the present absurdly complicated and cumbrous organisation which we call civilisation is needed to give mankind scope to develop its powers—some portion as men of science and philosophers, others as craftsmen and artists, and others again as good citizens and helpers of their fellow-men

# Sins of the Spirit. <sup>3n</sup>he Clash of Culture and the Contact of Races: an

Anthropological and Psychological Study of the Laws of Racial Adaptability, with special reference O to the Depopulation of the Pacific and the Govern-N ment of Subject Races. By George Henry Lane-Fox Pitt-Rivers. Pp. xiv + 312. (Londor.: teorge Routledge and Sons, Ltd., 1927.) 18s 10-4. CHORTLY after the War, Capt. Pitt-Rivers took a course at Oxford in psychological and anthropological studies. Thus equipped, and unleterred by the fact that he would be re-traversing the field of research in which had laboured the late W. H. R Rivers, one of the most brilliant of twentieth-century psychologists and anthropologists, he embarked for the South Pacific islands to undertake a further inquiry into the effect of the impact of alien peoples upon the indigenous tribes. The fruit of his researches is presented in this volume, which bears comparison with those of his famous predecessor for breadth treatment of subject matter, and exceeds them its clarity of expression and fearlessness of position. Capt. Pitt-Rivers's diagnosis of the implaint from which the primitive communities No. 3030, Vol. 120]

m Oceania are suffering, and his general conclusions regarding the effects of European exploitation and later well-intentioned British administration, are much the same as those of other objective observers; yet he achieves such novelty of treatment that his book must be read

There is a growing tendency among humanitarians in Europe and America to assume that 'native problems,' that is to say, native unrest and discontent, exist only in those territories where the native races are being dispossessed of their lands and exploited in the interests of white plantation owners and mining companies would reject the idea as preposterous that such exploitation, however cruel, may be less disastrous in its effects upon native morale than an intentionally benign administration or Christian missions. Such implicit faith have they in the perfection of our civil and religious institutions, so comments are they of the uplifting' influence of the conventional codes of their own society in introduced among primitive peoples, the large are are to ignore the possibility that there of the matrixes which are being catastrophically destroyed may be intrinsically more valuable to and more consonat with the natural development of native end " It may shake their secapiacency to "nowhere in the Pacific is the phendisappearance of the aboriginal ranable than in the islands of the Eiwhere Eur pean control I. a ... influence felt. In these Islands ecline, even during the last tween is well known and be attributed admitted official "nnot be attributed to "violence and s" , and civilised drink and diseases," to the disease Lord Olivier alleges he decrease of here population is due. These, of course, are in which cannot be disregarded, 'a 's there's doubt, avers Capt. Pitt-Rivers, apal cause in certain parts of the th. destruction of the "old-culture forms and en conmental conditions in the endeavour to impose too dissimilar a culture upon a people specialised by a long process of adaptation to particular conditions."

If there is one quality which differentiates the genume scientific worker from the rest of his fellows, it is his humility of approach to the problems which confront him. When an anthropologist, for example, studies native problems, the existence of differences between tribes and the manifest differences between races do not lead him hastily to assume that one particular culture form is superior to the rest and that it is in the best

interests of all peoples that they should conform to that one. As Pitt-Rivers says, "He studies native customs to discover their importance in relation to the social organisation of the people, and thereby discover what is essential to that organisation and the communal life of the tribe or race: to study their beliefs and their morality sympathetically in terms of their own thought, and without the desire to substitute for what is native something that is not native or adapted to native life."

There are certain aspects of the social life of most of the communities over which we exercise tutelage which shock the average European Nakedness and pre-nuptial licence, polygyny, consangumeous marriages, child-marriages, infanticide, are direct contradictions of our code of conventions Consequently, when confronted with racial degeneracy and depopulation, we attribute them to such 'evil' customs But, as Pitt-Rivers points out, these customs existed centuries before the advent of the Europeans, and apparently had no lethal effects. If the imposition of our conventions upon native communities, the introduction of our legal system, disciplinary, sanitary, and clinical measures, and our form of religion, are to be regarded as beneficial, there should be an increase of population. The hard fact is that in Oceania there is an obvious decrease.

This decrease supplies the author with his thesis—the lethal effects of culture-clash—and leads him to subject the native customs to searching analyses, more particularly those customs which we deem to be shocking. He defends polygamy and consangumeous marriages and discounts the idea that child-marriages and infanticide are intrinsically bad or lethal in effect among the communities where they are practised. Inbreeding, as he says, and quotes Westermarck in substantiation, has from the earliest historical times been practised most among kingly and chiefly castes, with the aim of maintaining the purity of blood of the ruling castes. Provided there is some motive and ideal of selection in mating, inbreeding is positively beneficial and not the reverse. Dealing with the effect of the Christian missionary, he says, "His first efforts are directed towards inculcating decency and modesty by creating a sense of shame. In other words, by inculcating flesh-consciousness and the virtue of concealment, the two sign-posts of Christian culture"

The later chapters of the book embrace a good deal that is of more general interest than specific application to the Polynesians. Nevertheless, they

will repay the most careful study even thou we may not be prepared to accept some of 'conclusions. The author has brought to the strong of 'psychological factors' a fresh mind. challenges the latest work of Spearman on "The Abilities of Man" with no little skill. On the subject of extrovert and introvert types he is most illuminating. But best of all is his scornful denunciation of Puritan intolerance and its narrowing and retarding effects on European culture.

Capt Pitt-Rivers is least convincing when dealing with sex-ratio, where he argues from insufficient biological foundation. Some of the statistics he quotes upon which he builds his theory are inadequate to the purpose. Occasionally also he makes sweeping generalisations which are not applicable to every primitive community. With certain parts of West Africa in mind, where the tendency is for the peoples to live in enormous towns, we cannot agree that "it is acknowledged that the tendency of native races of barbaric cultures is towards decentralisation." Again, some of us cannot share his views with regard to a "White Australia." The experiment in white colonisation in Queensland appears to have been most successful so far.

The publication of this volume can do nothing but good. It will shock the susceptibilities of many. That is an advantage. Anything which will arouse our colonial administrators from too smug complacency, anything which will persuade the Home authorities to select men for the Colonial service who have been trained to seek for knowledge, to regard the customs of the native peoples whose interests they should serve as an integral part of their culture and one of the greatest factors in determining their will to live, should be heartily welcomed not only by anthropologists but also by all other scientific workers.

If a suggestion to the author may be made, it is that he should now carry out similar researches in Africa. They are badly needed.

A G. CHURCH.

#### Modern Acoustics.

Sound: a Physical Text-Book By Dr. E († Richardson Pp. vii + 286 (London . Edward Arnold and Co , 1927) 15s net

O long as sound forms the most rapid means of communicating thought from one norms human being to another, the subject of acoustic cannot fail to be important. Nevertheless, after the

No 3030, Vol. 1201

ime of the publication of the classical treatises of elmholtz and Rayleigh, it received little attention thav problems and raised many difficulties in the practical application of the older knowledge. A dreary feature of the pre-War text-books on the subject was the neglect of researches carried out after about 1890. It is therefore a great pleasure to find that Dr. Richardson's book is a wellbalanced account of the present state of knowledge in experimental acoustics rather than still another of what may be called the Rayleigh-without-tears type of book. We must not complain that in this volume there is too little of Rayleigh, that is, too little mathematical treatment, for the sub-title is "A Physical Text-Book." The author claims that it covers all that a candidate for the pass and honours degree examinations of British and American universities should need In actual practice the English degree student can omit the subject of acoustics, and even if the subject is not omitted altogether there is not time for a full treatment such as is here given. The student needs rather a short book dealing with a few of the main topics together with laboratory experiments and problems for solution. Neither of the two latter are given in this volume

The book is more likely to be of service to the research student, the research worker, and the technician, as it is the only source of information in English of the results so far attained in any branch of the subject, together with copious references to the original papers. Since almost all the important work has been included, it is of interest to note the many problems which are still unsolved, due partly to the neglect of acoustics as a field of research. A fallacy exists in the minds of many physicists that in order to research successfully in this subject one must possess a 'musical ear.' When we see how such a genius as Helmholtz was misled by trusting to his ears, we cannot but wish that much acoustical research would be done by deaf workers, who would be almost compelled to attempt only quantitative measurements. In truth, the ear is not a scientific instrument, although it is a wonderfully sensitive apparatus, the powers of which are well summarised in the chapter on subjective sound. Much remains to be elucidated in the subjects of speech and of hearing.

Another big unsolved problem is that of sound recording. The ease with which one can set up a light membrane, and by coupling it with a suitable optical system, obtain pleasing curves upon photographic films, has misled many workers into

thinking that the curves represent the impinging sound waves Dr. Richardson rightly concludes that the phonodeik is the most accurate sound recorder of the phonograph type, but even this wonderfully delicate instrument was calibrated by a set of organ-pipes, and it was recently stated that at the National Physical Laboratory the organ-pipe as a standard source of sound had to be abandoned. The author shows kindness in omitting to mention one big memoir describing work in which gramophone records were used to study sound waves, and in which the method was fallaciously claimed to be good because by playing the record upon a gramophone and listening to it one could tell how nearly the indentations of the record represented the actual sounds originally recorded. It is safe to say that present we have neither a perfect recording ir ment nor a trustworthy standard source with the to test our imperfect instruments. Such as the later are well described in the chapter and vs. a sound in air. One should have like a fuller treasment of the condenser micropanae, in tailing that of H. Riegger, which differ, considerably from the Wente type mentioned An adequate treatment would have required a good deal of space, it is subject is important. It dis projectiess amonification. would have many value be applications

Electrical devices in general have aboutly been of great service in acoustical research. The best attempts described in the book at a plute energy men, arements which are no diff. It because of the not the absorpte value of the energy of a sound w ... A normal intercity, are repend upon electrical dev. . . In almost every chapter occur references to the use of electrical instruments such as the electro-magnet and the valve for maintaining the vibrations of uning-forks, diaphragms, bars and strings, the oscillograph, the Einthoven string galvanometer, the stroboscope, the piezo-electric oscillator and instruments depending on the change in the electrical resistance of a heated wire over which sound waves pass. As in so many other branches of physics, photography also has given much help, particularly in the recording of vibration and in the instantaneous spark photography of density changes in vibrating gases.

Special chapters are devoted to heat-maintained sounds and to æolian tones, the latter chapter wisely preceded by a discussion of vortex formation and Prandtl's work on viscous fluids. This had not previously found its way into the text-books of physics, despite the test of twenty years' successful application in aeronautics

Well-written sections dealing with the various

musical instruments are included. It might perhaps be better to omit such chapters from physical text-books, as their interest is more restricted than other branches of acoustics and their inclusion helps to spread the fallacy that acoustics is a subject for the musical physicist only. such the meagre information available is merely a source of irritation. Because we have a good deal of knowledge of the motions of bowed and struck strings, we must not assume that we understand the acoustics of the violin or the pianoforte. A gut violin string radiates none of its energy to the air, and a steel piano string radiates but little. There are many complex changes between the string and the listener's ear The problem of the special properties of a good Strad violin still defeats us. Le strings clearly do not hold the secret, for they are the same as are used upon any violin. Musical acoustics is best to intimate mixture of physics, p si \_\_ology.

The book dable, is well produced, and can be heartily mended to all interested in the surface. Technical haders and little or no mathems knowledge are 1green of difficulty in follow, almost the whole inerconnaise treatment. The honos degree sturistical treatments of Lamb or kindall ("Vibrating Systems and Sound," 1927), was to the research worker will need also Auerbach's "All stacs," 1907, and the eighth volume "Akustice" on the Geiger and Scheele "Handbuch der Physik" 192.

W. H GEORGE.

# A Canine Encyclopædia.

Dogs: their History and Development. By Edward C. Ash. Vol. 1. Pp xviii+384+108 plates. Vol. 2. Pp. xvi + 385-778 + plates 109-160. (London: Ernest Benn, Ltd, 1927.) 105s. net; edition de luxe, 252s. net.

In these two bulky volumes, Mr. Ash has for the most part succeeded in tracing the histories of practically all the domesticated varieties of dogs which are known at the present day. In an opening chapter on the origin and evolution of dogs as a whole, in which he quotes many well-known authorities, he puts aside Mivart's wolf-jackal ancestry theory in favour of a hypothesis that the ancestors of modern dogs probably existed in Eocene and Miocene times and were closely related to Cynodictus, Amphicyon, Simicyon, and Cynodesmus. It would seem, however, that in view of the rapidity with which change takes place in animals under domestication and artificial selec-

tion, there is no necessity to go back very fa<sup>2</sup>7 beyond historic times to find the ancestor of the modern dog, in all its variations, among the wolves and jackals, especially when one considers, as Mr. Ash points out later on in his second volume, that breeds so different as the Yorkshire, the Airedale, and bull terrier have all been 'made' during the past hundred years, and that the so-called Alsatian wolf-hound, more properly known as the German sheepdog, has only been in existence a little more than a quarter of a century.

Again, a comparison of some of the figures of typical dogs of a hundred years ago with those of their modern representatives shows that the type in many cases has changed to such a marked degree that the two might easily represent entirely different breeds. On the contrary, where the type became stabilised many years ago and artificial selection has been carefully carried on by man, as in the case of some of the members of the greyhound group, which are one of the oldest of all breeds, there appears to have been very little change in general appearance between the dogs of to-day and those of 6000 years ago

In view of the publicity which has been given to Alsatians in the daily press of late, it is interesting to note that Mr Ash says: "There seems to me to be little doubt that the Alsatian type was obtained or developed at some distant time by wolf and/or, dingo crosses," and goes on to quote that the greatgranddam of the famous Alsatian "Hector Von Wohlen" was the result of a cross between a dogwolf and an Alsatian bitch.

The book is not written merely for the technician; it will have an appeal for all dog-lovers, for Mr. Ash's researches have led him to study the dog from many aspects. There are chapters on dogs in relation to religion, medicine, law, and history in general. We learn that in Wales a certain cure for a cough is to put a hair of the patient's head between two slices of bread and give the sandwich to a dog, and also that the hair of a dog when burnt is a sure remedy when applied to a bite. The Chinese seem long ago to have come very near to Pasteur's great discovery. "If a man was hurt by a mad dog, then the man goes mad, the best cure was to use the brain from the same dog and put it on the wound."

As a work of reference the dog breeder will find Mr Ash's book invaluable, for in addition to the histories of all breeds, there are lengthy appendices in which show points, pedigrees of famous dogs. 5 and championship winners are given. The book the worthy of a bibliography and it is to be regre

at none is given, the only references being attered notes in the text and rather inadequate accountees

There are more than 150 excellent plates, in which are figured several hundred dogs, from those of ancient Assyria and Egypt down to the living championship winners of to-day. These have been collected from many sources, and they alone testify to the care and perseverance which have gone to the building of what will doubtless be a classical work on dogs and one which should find its way to every good reference library, as well as to the shelves of every dog-lover who can afford it.

### Local Floras.

- (1) The Flora of Buckinghamshire. with Biographical Notices of Those who have contributed to its Botany during the Last Three Centuries. By Dr George Claridge Druce Pp. exxvii + 437. (Arbroath: T. Buncle and Co., 1926.) n.p.
- (2) The Field-Club Flora of the Lothians. By the Botanical Committee of the Edinburgh Natural History Society Edited by Isa H. Martin. Pp viii + 142. (Edinburgh and London: William Blackwood and Sons, Ltd, 1927) 5s net.
- (1) TO be the author of three complete county floras is an achievement which we believe to be unique in the annals of British botany, although C. C Babington, in addition to his floras of Cambridgeshire and the Channel Islands, compiled the catalogue known as the "Flora Bathoniensis." The present flora is the third from the pen of Dr. Druce, whose flora of Oxfordshire was published in 1886 and the flora of Berkshire in 1897. A flora of Buckinghamshire is the m welcome as no previous flora has ever been putlished of the county, though a catalogue species without localities was issued by the Mr James Britten in 1867 under the title "Flora of Buckinghamshire." The work before a contains records of about 930 species, exclusive of aliens and the microspecies of Rubus and Taraxacum, or slightly more than the number recorded by Pryor for the neighbouring county of Hertford.

To the student of geographical distribution, the most interesting species of the area is Danaa cornubiense (Physospermum aquilegifolium), which is otherwise confined in Britain to Cornwall and Devon. The flourishing condition of this plant in its one station is, we may note, rendered significant by the fact that several 'western' species occupy their eastern limit at Burnham Beeches also. This is shown by the occurrence there of the liverwort

Microlejeunea ulicina, or the very rare snail Vitrina major, in company with the north-western molluse Acanthinula lamellata Of the extinct and diminishing species, it is of interest to note that plants of wet habitats predominate, as was shown to obtain in the neighbouring county of Hertford. The introduction contains a brief account of the contributions to the botanical knowledge of the county, in which a short autobiography of Dr. Druce is of especial interest.

This work emphasises once more the debt that British field botany owes to the pharmaceutical profession in general and to the author in particular.

(2) "The Field-Club Flora of the Lothians" is a much smaller work, of a size convenient for the pocket, and embodies the records of the Edinburgh Natural History Society. Localities are given, and a few ecological lists for some selected stations are furnished. Some eight species are noted as having recently become apparently extinct, any aget which we may note especially Corallorrhi innut. Lin næa borealis, Tecsdalia nudica s, t cambe mu' tima, Genista pilosa, "That is a tavum. and att. to be regretted the this little book w east i by the mi necessary inclusion a gloslary and we do plates illustrativ of the botanical term . ... bear no relaty on the main text and or see adequate to La comprehension of a disυra. Neverthelist. despite the diminished nience, field becauses will welcome this ada in to our local flora. E. J. S.

#### 

pphances. By P. M. 170. (London: Crosby 1927.) 36s. net.

\* extremely varied, albeit highly of vessel, interesting alike to the t, the engineer, and the shipbuilder. on the subject of dredger design is, far from voluminous and, indeed, is able more for its paucity than for its fullness. '1: ce is abundant scope, then, for the volume by Mr. Dekker, and his description of a number of present-day dredging vessels and appliances forms a useful addition to the reference library of the practising engineer. It will be felt, on perusal, that the book is, in fact, mainly descriptive, and that it concentrates largely on individual examples of dredger construction. This does not detract from the utility of the work as a practical directory to the subject, but it still leaves the field open for a dissertation on the principles underlying dredger design. Such a work would, perhaps, be special province of the naval architect.

Mr. Dekker's book is not divided into chapters,

but is in two parts, with numerous sub-sections. Commencing with a historical résumé and account of early types, the modern bucket dredger is then subjected to analytical description, followed by similar treatment of the sand pump, the suction dredger, and the suction cutter dredger. There is no reference to the dipper dredger, the type so prominently in vogue in North America. No doubt this is due to the author's Dutch nationality and his intention, expressed in the preface, of giving solely an account of the development of dredging appliances in Holland. He points out that "as regards the more recent development, England and Holland may safely claim to have made the greatest progress." A number of interesting photographs and line drawings enhance the attraction of the book. BRYSSON CUNNINGHAM.

The Father in Primitive Psychology. By Prof. B. Malinowski. (Psyche Mimatures, General Series, No 8.) Pp. 93. (London: Kegan Paul and Co., Ltd., 1927.) 2s. 6d. net.

Savages, to use a popular term, are no more logical nd consist t than civilised peoples. This is a soint which is often overlooked and has been usefully emphasised by Prof. Malinowski on more than one occasion. Ever since it has been recorded that some primitive people norant of the part of the male in procreation, obvious difficulties which it is thought shou... ritably arise have caused some doubts as to the apleteness of this alleged ignorance. In this boo. Prof. Malinowski records the results of his inquiric, on the subject . ....ng the people of the Trobrianc Islands, with special reference to its bearing upon the position of the father as a purely sociological and not a biological factor in the family group. The results are extremely interesting, and if Prof. Malinowski has not been successful in disposing of all, he has at any rate solved some of the more serious difficulties. The case of the unmarried mother is still a stumblingblock, and the author has to fall back upon the explanation that a birth is contrary to the custom of society, a force which, when everything is taken into account, does not seem quite adequate, strong as it undoubtedly is. Prof. Malinowski has some illuminating remarks to make on the relation of this lack of physiological knowledge to the attitude of the natives towards Christianity.

Relativity: an Exposition without Mathematics. By Prof. James Rice. (Benn's Sixpenny Library, No. 105.) Pp. 79. (London: Ernest Benn, Ltd., 1927.) 6d.

In this paper-covered pamphlet of eighty pages, which is sold for sixpence, Prof. Rice sets forth the doctrine of relativity: and not only this, but also (as preliminaries to it) the principles of Newtonian physics, the history of optics in the nineteenth century, and the Maxwell-Lorentz theory of electricity. It is a wonderful performance—judicious, scholarly, well written, and sparkling with apt arisons and illustrations. A little master-piece in every way.

In the expectation that it will be continually

reprinted, and translated into every language und the sun, we venture to point out one or two thing which might be amended On page 13, after correctly describing FitzGerald as "an Irish physicist," the author refers to Larmor as "an English mathematician at Cambridge" Larmor is, however, another Irishman. On pages 51-52 we are told that the mass of the electron has been proved by experiment to be wholly electromagnetic: we do not understand what Prof. Rice means by this: at any rate, the Kaufmann-Bucherer experiments on the mass of  $\beta$ -particles merely show that their mass varies with velocity in the way that any mass, whatever be its origin, must do according to the relativity theory. On page 73, latitude is obviously a slip for *longitude*.

Elementary Practical Physical Chemistry. By Dr. James Frederick Spencer. (Bell's Natural Science Series.) Pp. viii + 263. (London G. Bell and Sons, Ltd., 1927.) 5s.

Dr. J. F. Spencer has written a very attractive book of practical exercises in physical chemistry. It is an elementary book, describing experiments which can be performed by boys and girls in the upper forms of schools. For this reason, complicated apparatus and tedious experiments have been avoided, and in certain cases new types of simple apparatus have been designed and put on the market, to enable additional experiments to be made. Since the requirements and possibilities of an elementary course in physical chemistry have now been to a large extent standardised, the detailed setting out of the work is more important than its scope, and for this reason Dr. Spencer may be congratulated on the clearness of the 89 diagrams which serve as illustrations to the 100 experiments, for which detailed instructions are given in the narrative of the text. The final test of such a book can only be applied under conditions of 'active service' in the laboratory, but from a preliminary inspection it appears likely that this test will be passed with credit, to the mutual advantage of all those who may be concerned in the enterprise.

Über die Warme-Leitungsfahigkeit der Metalle. Arbeiten von G. Wiedemann und R. Franz. Herausgegeben von Prof. Dr. Arthur Wehnelt. (Ostwald's Klassiker der exakten Wissenschaften, Nr. 222.) Pp. iii + 39. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1927) 2.80 gold marks.

The first requirement of any theory of the conduction of heat and electricity in metals is that it shall satisfy the law discovered by Wiedemann and Franz in 1853, that metals have the same conductivity for heat and for electricity. Although modern determinations have shown that the law is approximate only, it is most appropriate that the original paper should be republished and made widely available. The editor, Prof Wehnelt, has added a short life of Prof. Wiedemann and a few notes as to more recent work on the same subject.

#### Letters to the Editor.

[The Edutor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

# Discovery of the Function of the Pycnia of the Rust Fungi.

In a letter to Nature, published July 23, 1927, I do. d, on the basis of experimental evidence, that waking helianthi is heterothallic. The results of other experiments now enable me to state definitely nat Puccinia graminis is also heterothallic. Moreover, nee my first letter was written, proof has been obned that the pycnia (spermogonia) of the Rust gi are not, as many botanists have supposed conceptacles producing non-functional spermatia, reactive organs having a non-male function they carry out through the agency of flies. covery was made as follows.

y 1927, I had a large number of sunflower angs, upon the young foliage leaves of which there were many pustules of Puccinia helianthi. Each pustule had originated from a single sporndium and had numerous pyonia on its upper surface, and every pyonium had excreted a drop of nectar containing pyonospores. Theoretically, as set forth in my former letter, it seemed reasonable to suppose that the mycelium, pyonia, and pyonospores of some of the pustules were (+) in sex, whereas the mycelium, pyonia, and pyonospores of other pustules were (-) in sex.

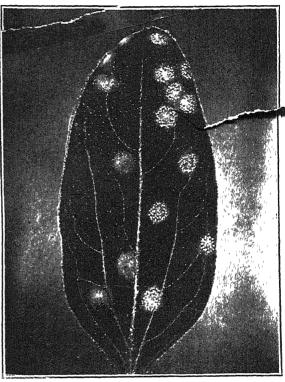

On May 17, Prof. A. H. Reginald Buller, of the University of Manitoba, was in the greenhouse of the Dominion Rust Research Laboratory inspecting the experiments in progress. A solitary fly, one of the first to appear after the winter season, had entered the greenhouse. Prof. Buller directed my attention to the fact that the fly was settling on the sunflower leaves, sipping nectar at the pycnia of one pustule and then flying off to another leaf and sipping the nectar of the pycnia of another pustule, and he at once said: "The solution of the problem of the function of the pycnium is an entomological one. Copy the action of the formulation and (-) pycnium special (-) pycnium and (-) pycnium special (-) pycnium and (-) pycnium

In two sets of experiments with Puccinia heliminion sunflower leaves, pustules of menosportial origin, each pustule having developed numerous pyenia but no æcia, were treated as follows: in 184 pustules the pyenospore-containing nectar was mixed with the help of a scalpel, the nectar of any one pustule being mixed with nectar of several other pustules; while, as a control, in 174 pustules the nectar of each pustule was stirred up with a scalpel, but not mixed with any other nectar, the scalpel being carefully sterilised before each operation.

Five days after the experiment had begun, the condition of the pustules was as follows: of the 184 mixed pustules 176 had produced æcia, 4 no æcia, and 4 had wilted and died through leaf-injury; of the 174 unmixed pustules only 20 had produced æcia,

while 154 were entirely free from æcia. Under normal conditions when the nectar is neither mixed nor stirred, a certain percentage of monosporidial pustules always produces æcia, as already recorded in my first letter. The appearance of æcia in 20 of the unmixed pustules was therefore in agreement with expectation.

From the experiments just recorded it is clear that mixing the pycnospore-containing nectar leads with rapidity and considerable certainty to the development of æcia. While the pycnospores are haploid, the æciospores are diploid. We can therefore also say that mixing the pycnial nectar causes each public of monosporidial origin to change from the haploid to the diploid phase.

The 1. - the ter our or saturdan - Thank x 11

Experiment, singuar to those pure described navo been under with Puccinia graminis on barberry reave. The one set of experiments the pychial nectar of 110 monosportual pustules was mixed; while, as a control, the pychial nector of each of 35 mosporidial pustules was stirred up separately but not mixed.

"Six days after the experient had begun, the condition of the pustules had broduced seen and 14 no sein; whereas of the 85 unmixed pustules only 17 had produced seein, while 68 were free from sein.

In the experiments with *Puccinia graminis* just described we again have clear evidence of the function of the pycnia; for, when the nectar is mixed, æcia are rapidly formed in most of the pustules, whereas when the nectar is not mixed, most of the pustules do not develop æcia. A certain percentage of mixed pustules always produces æcia, as in *Publianthi*.

In Fig. 1 is shown the under side of a sunfig. The leaf was inoculated with sporidia of

helianthi on July 9. Each pustule originated from a single sporidium and was therefore unisexual. On July 29 the pycnial nectar of the ten pustules on the right side of the leaf was well mixed, while, as a control, the pycnial nectar of each of the six pustules on the left side of the leaf was stirred separately but not mixed. On Aug. 3 the leaf had the appearance shown in Fig. 1, and on Aug. 4 the photograph was taken. This experiment again clearly demonstrates that the pycnia are functional, in that their pycnosporecontaining nectar, when transferred from one pustule to another, brings on the diploid phase as shown by the appearance of æcia within five days of the

In Fig. 2 is shown the under side of a barberry leaf. The leaf was moculated with sporidia of Puccinia

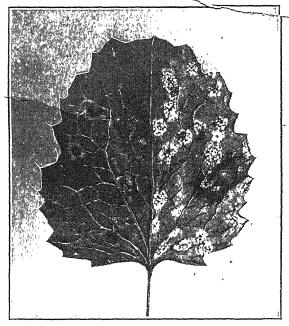

Fig. 2 —Under side of a barberry leaf. × 2.

graminis on Aug. 2. Each pustule originated from a single sporidium and was therefore unisexual. Up to Aug. 19 one pustule on the right side of the leaf had produced acia. On that day, the pycnial nectar of all the pustules on the right side of the leaf was well mixed; while, as a control, the pycnial nectar of each of the eight pustules on the left side of the leaf was stirred separately but not so red and 28 the leaf was about the appearance show the sto Nati The idicat of mixing the pycnial nectative as of Earlyt: It is appeared on the right side of that such mixing had been effected, but not on the left side where mixing had been avoided.

Proof that flies mix the pycnial nectar of separate

unisexual pustules and so cause the pustules to change from the haploid to the diploid phase, as shown by the appearance of æcia, was obtained with Puccinia

helianthi as follows:

Fifteen to twenty flies were enclosed in a large screen-wire cage with about twelve pots of sunflower seedlings, on the foliage leaves of which there were monosporidial pustules bearing pycnia but no As a control, flies were kept out of another reen-wire cage which contained fifteen pots of seedlings, on the foliage leaves of which 159 similar pustules.

Eight days after the beginning of the experiment 96 of the 98 pustules to which flies had had access had produced æcia and only 2 pustules no æcia, whereas only 5 of the 159 pustules to which flies had not had access had produced æcia.

It was found that in *Puccinia helianthi*, and also in *P. graminis*, nectar which had been heated to 70° C. to kill the pycnospores is not effective in including the production of æcia when mixed with the nectar of other pycnia on the living leaf. This indicates that it is the pycnospores which are the effective agents in inducing the formation of aecia, and not the necta

In a series of experiments with Puccinia heliant and in another series with P. graminis, the pycn nectar of one monosporidial pustule was removed in capillary tube and divided into several drops, and the the drops were applied singly to the pycnia of as mar pustules as there were drops. In response to t treatment some of the pustules produced acia others did not, thus indicating that the pycnos are of two kinds (+) and (-). The full det these experiments will in recorded elsewhere.

It appears that, under natura conditions, t three ways in which pustules of monosperid may change from the haploid to the diploid conui-(1) by a (+) sporidium and a (-) sporidium settling or a leaf close together, so that they form pustules which coalesce in such a way that the (+) mycelium and the (-) mycelium come into contact directly; (2) by means of flies which carry (+) pycnospores from one isolated pustule to the ( - ) pyonia of another isolated pustule or, conversely, ( - ) pyonospores of one isolated pustule to the (+) pycnia of another isolated pustule: and (3) spontaneously. The cause of the spontaneous change of a certain number of the pustules of Puccinia helianthi and of Puccinia graminis from the haploid to the diploid condition is at present unknown, but the phenomenon finds its parallel among the Hymenomycetes in Coprinus radians investigated by Vandendries and in C. Rostrupianus investigated by D. E. Newton.

The pyenia attract flies and reward them for their visits in very much the same way as do flowers or the Stinkhorn Fungus. They occur chiefly on the upper side of the leaves, where they are readily accessible to insects; they are usually yellow or red in colour, by which means—and perhaps also by the refraction and reflection of light in the drops of nectar-they are made conspicuous; in some species, e.g. Puccinia suaveolens, and possibly in many, they will an attractive odour, while, finally, they nectar contains sugar, and on this account avidity.

It has long been remarked In those rust fungi producing organs to appear. Since they play such an important part in changing the haplophase into the diplophase and in inducing the formation of meia, their appearance on the mycelium before the acia can now be readily understood. Pycnia procede acia, because by pycnial action acia are formed.

The crossing of two physiological forms of Puccinia

graminis, etc., might be effected in the following relatively simple manner: obtain monosporidial pustules of both strains and then mix the pyenial nectar of a (+) pustule of one strain with the nectar of a (-) pustule of the other strain, or, conversely, mux the nectar of a (-) pustule of one strain with the nectar of a (+) pustule of the other strain.

In my previous letter to NATURE I stated that, in Puccinia helianthi, the eciospores which had appeared in at least some of the acia of pustules of mono-sporidial origin are unnucleate. Further cytological experience has convinced me that the apparent

uninucleate condition of these æciospores was due to an artefact. The young ecrospores near the spore-bed of every æcium of monosporidial origin that I have investigated more recently have all proved to be

In conclusion, I desire to thank Prof. Buller for assisting me with valuable suggestions and helpful criticism

J. H. CRAIGIE.

The Dominion Rust Research Laboratory, Winnipeg, Oct. 13.

### The Cellulose Space Lattice of Plant Fibres.

Two different types of X-ray diffraction patterns and their interpretations, made from cellulose fibres, have appeared in the literature; one associated with a 'point diagram,' presented by R. O. Herzog, the other, with a 'line diffraction pattern,' by the writer 2

Although the two methods used were slightly different, both depend upon 'reflection' of monochromatic X from the uniformly spaced planes of atoms in the fibres, and should therefore be capable identical interpretation. The data in general are in fair agreement, except in two or three examples where the differences cannot be accounted for by experimental errors It is the purpose of this communication to direct attention to this lack of agreement, and to point out its effect upon the lattice structure proposed by Herzog.

In the Journal of Physical Chemistry, April 1926, pp. 455-467, Herzog discusses a lattice for cellulose which he considers a revision of his earlier work. In the data for this revised lattice there appears a series of interference points which are associated with planes parallel to the c axis of the elementary cell; that is, planes parallel to the long axis of the fibres. In that series particular attention is directed to points  $A_3$  and  $A_4$ . The data given below were taken from his Table I., and from them the interplanar spacings d were computed by means of the Bragg formula:

$$n\lambda = 2d \sin \theta$$
.

where  $\theta$  is the glancing angle, and  $\lambda = 1.54$  A. the K<sub>α</sub> wave-length for copper, since the radiation used was from a copper target.

Point.	$\operatorname{Sin} \theta$	d
$A_3$	0.17909	4·30 A.
$A_4$	0.1981	3 89

In the other type of diffraction pattern, as published m the Journal of General Physiology, Nov. 1925, pp. 221-233, and May 1926, pp. 677-695, I found no line corresponding to the 4.30 interplanar value for planes which were parallel to the long axis of the fibres. In making these patterns the X-ray beam was passed through a filter to ensure a monochromatic beam of Ka wave-lengths only. When, however, diffraction patterns were made later with the unfiltered radiation, a line which corresponded to the 4 30 value always appeared prominently. Since this interference maximum failed to appear when Ka wave-lengths only were used, and on the other hand always appeared clearly when the beam was a composite of all of its wave-lengths, it was suspected immediately that a single set of planes with strong reflecting powers had produced two interference lines, one from the  $K_{\alpha}$ , the other from the Ks wave-lengths.

No. 3030, Vol. 120]

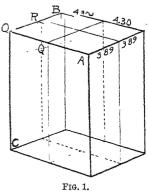

Calculation shows that the point A3 might have been produced by the Ks wave-lengths from the very strong 3.89 planes,

Point.	$\sin \theta$ .	$K_{\alpha}$ $\lambda = 1.54 A$ .	$K_{\beta}$ $\lambda = 139 A$ .
$A_3$	0 17909	4.30	3.89
Δ.	0.1981	3.89	

and since no line was found corresponding to the  ${\rm A_3}$  point when the Ks wave-lengths were filtered out of the beam, one must conclude that Herzog failed to recognise the Ks origin of the As point and gave it

the 4 30 value as though it were of Ka origin That value, therefore, should be discarded from the data.

Attention was directed to a similar use of-a Ks interference point (NATURE, Aug. 15, 1925, 243) in the original data of Herzog and Janeke which was published in Zeitsch. fur Physik, 3-3, 196-198, 1920, and m which incidentally this 430 value does not appear. That value apparently had been discarded at that time as of Ks origin.

When, however, one attempts to discard the 4.30 value now, a new importance is found placed upon it. The dimensions for the axes of the revised elementary cell as proposed by Herzog are given as  $a:b:c=8\ 60:7.78:10.22$ . This elementary cell may be represented by Fig. 1, where

$$OA = a = 8.60 = 2 \times 4.30$$
  
 $OB = b = 7.78 = 2 \times 3.89$ 

The two planes passing through Q and A respectively and parallel to the plane OBC are considered as being separated by the 4 30 distances, OQ and QA. Likewise OR and RB are the 3.89 distances. That the a axis is directly associated with the 4.30 value and the b axis with the 3.89 value is definitely fixed by the indices (200) and (020) respectively, given in his Table II.

It seems, then, that the values used for the a axis and the b axis of the elementary cell proposed were both produced by the same set of planes, and when the 4.30 value is discarded, as it seems evident that it must be, the axial dimensions proposed by Herzog lose their significance, and therefore a number of conclusions must be discarded. (1) That four se units are contained in the elementary anhydic 5. cell is now of co with casumptions that certain, terfer produced by impurities in the first state of the control of the contro (2) The -re are two types of carbohydrates en \_ cellulose of the fibre, are now also variout adequate basis. (3) The correspondence between the 4.30 value and a certain interference maximum obtained from mercerised cellulose likewise now has no significance. These conclusions at least must be discarded if the only basis for them lies in the elementary cell as suggested by Herzog. A lattice based upon the 'line diffraction patterns' seems to be in better agreement with the properties of the fibres, both physical and chemical. This structure is discussed in detail Sponsler and Dore in "Colloid Symposium," graph 4, pp. 174-202, 1926, and in the mentioned above. mentioned above.

#### The Lower Palæolithic Implements of Sligo.

When we published in Nature an account of the discovery of Lower Palæolithic Implements in Ireland, we expected that the announcement would give rise to a certain amount of disturbance among the more old-fashioned archeologists of that country, but we did not contemplate, or believe it possible, that this announcement would result in the appearance (NATURE, Nov. 5, pp. 652-3) of such a series of statements as that to which Prof. Macalister and his associates have been so unwise as to append their signatures. Incredible as it may appear, it is nevertheress a fact, as is clear from the particulars published in NATURE (NUV. 5), that these investigators have not even correctly located the site at Rosses Point, Sligo, where the collapsed rock shelter exists, the details of which, as given in NATURE (Aug. 20), are preserved m excellent photographic and other records, which are to be made public shortly in the memoir to be published by us, but have mistaken the promontory of The Rosses for Rosses Point, which constitutes the northern projection of the former. Prof. Macalister and his associates clearly indicate in their note in NATURE that they visited this spot unknowingly, and thus failed to observe the collapsed rock shelteror the Raised Beach of powdered shells. In view of this faulty observation it is not surprising to find that these investigators state that "there is no Raised Beach...in the district." This claim, however, is in direct opposition to the opinion expressed in the Geological Survey Memoir, "The Counties of Sligo and Leitrim," p. 27.

Prof. Macalister and his associates are clearly, therefore, engaged in the abortive task of attempting to criticise a site which has not been dealt with by When they were confronted with the fact of the discovery of paleolithic implements in (a) a rock-shelter, and (b) Boulder Clay in Sligo, the only course they could take in order to support the ancient order of archæology was quite obvious. All they imagined must be done was to deny that the rock-shelter is ancient, and that the specimens found in it, and in the Boulder Clay, are humanly flaked. It is true that these are matters open to discussion, but we have confidence that competent archæologists, not unscientifically determmed to deny the presence of palæolithic implements in Ireland, will give little heed to the arguments and assertions of Prof. Macalister and his In fact, all those with the requisite associates. knowledge enabling them to give a judgment of value upon the matter have, without one exception, at once accepted the Sligo specimens as of human origin.

As an example of the confusion of thought of our opponents, it may be pointed out that in neither of our note our note of the many be pointed out that in neither of our note of the statement of the relevance, or importance, of the statement that Mousterian artefacts are not as a rule of impressive size. Do our critics wish to suggest that this prevents the Sligo specimens from being regarded as of this age, and further, do they claim that the examples of very large implements from High Lodge, Suffolk, and other places, including Le Moustier itself, are also barred from a Mousterian status? As for the assertion that the change of colour coduced on the surfaces of stones by weathering is to be described as 'patination,' this is a dogmatic unsupported, as are most of the statements

in the note under discussion, by any

It is not for us to explain why the palaeolithic people of Sligo chose to flake limestone into implements, or to give reasons why the efforts of Prof. Macalister and his associates failed to produce a conchoidal fracture in this material. But the fact remains that the ancient people did both these things, not once but many times, as may be seen by an examination of the material collected in Sligo, and exhibited at the rooms of the Society of Antiquaries of London until Dec. 6.

We, of course, regret that our critics failed to find any artefacts when visiting the Sligo coast, but this is possible of explanation on two grounds: either that the previous searching was so thorough as to leave nothing to be found, or-as is more probable because Prof. Macalister and his associates did not know what to look for and preserve. It is not necessary for any demonstration to be given of the manner in which the Sligo specimens were flaked, as a swardy of these by anyone familiar with the flaking of stone will show clearly, and beyond any question, that the method utcombed in Nature (Sept. 24) was indeed carried out in ancient times. Further, it is to be doubted—even if such a demonstration were given—whether Prof. Macalister and his accounter would understand it. They are evidently unfamilia. with the Mousterian technique by means of which Levallois flake-implements were detached from prepared cores. The Sligo method-with two minor differences—is absolutely true to type, yet our critics describe it as 'complex.' This it may appear to them, but it is otherwise with archeologists who have made a study of these matters.

Prof. Macalister and his associates, with a thoroughgoing disregard of ordinary scientific procedure which would have necessitated an examination of the Sligo specimens before passing judgment upon them, nevertheless do not shrink from inforring, in the columns of NATURE, that they are of natural origin. On the other hand, their supporter, Mr. Warren, regards the same specimens, with the exception of those found in Boulder Clay at Ballyconnell, as made by man This, to say the 'east, is unfortunate, especially in view of the inherently had case which our critics have to defend. Lastly, we may direct attention to Mr. Warren's statement that, apropos of the Sligo material, there is "no passable resemblance m any one of these flakings to any form of prehistoric implement, either palæolithic or neolithic." strange claim is indeed a classic example of the truth of the saying that given sufficient rope, certain people are bound to hang themselves Anyone interested in this matter who has visited the exhibition of th Sligo specimens at Burlington House will, we have no doubt, agree with us that Mr. Warren, togethe with Prof. Macalister and his associates, have suspended themselves in a very thorough and fatal manner.

#### Manoilow's Blood-test for Sex.

In Nature of Nov. 5, Mr. Perkins makes a valuable contribution to the study of chemical manifestations associated with sex, but he gives an erroneous impression of Dr. Manoilow's work on sex-identification by blood-tests in two respects. (As I am in possession of a recent review of this work by Manoilow hunself, which it is hoped to publish soon, I am able to correct these wrong impressions.) In the first place, the workers mentioned by Perkins are mostly disciples, who have merely either applied

Manoilow's technique to some additional organisms, or have attempted to reduce the complicated reaction evolved by Manoilow to a simpler one. In the second place, Manollow worked for some years on the serum of "cows and oxen, horses, cocks and hens," as well as man, before he published (Wratchebnaia Gazeta (Medical Journal), 15, 21-22; 1923) the earlier accounts of his work on the identification of sex in man and other animals by a biological reaction of the blood.

In discussing the results of applying his test, Manoilow shows that although in some categories of individuals—as those furnishing samples of blood from venereal clinics—he was able to determine sex accurately in 100 per cent. of cases, in others the percentage of accurate determinations was less than 100, but in the latter instances the degree of accuracy is high, and mostly significant. It is clear, therefore, that Manoilow has discovered a series of phenomena of fundamental importance in the study of sex, whether his test be infallible or not. The word liscovery is used advisedly, because the problem was attacked deliberately. Whether this reaction be was attacked deliberately. Whether this reaction be found—ve: ually to define particular sex-attributes or sex-products, or only a particular metabolic condition closely associated with sex, we are indebted to Manoilów for epening up this avenue of research, the vista of which beckons with the promise of great results in the future.

Now the reaction as evolved by Manoilow is not only delicate, as Perkins points out, but also intricate, and it is doubtful whether any worker would attain to the original researcher's standard of success in its use, without both meticulous attention to the detail of the test, and considerable experience in applying it. It is the object of the account mentioned above to present to English workers full details of the test.

At about the time Manoilow succeeded with his test for sex, it was suggested independently in Nature 'vol. 111, p. 879; 1923) that a chemical test for sex 1. ight be found to be possible in invertebrates, because of the common occurrence of a difference in colour of the pigments in the gonad of males and females of the same species. Thus the underlying idea of this suggestion was not that a universal test might be found for sex, but rather that specific chemical tests might be devised for differentiating sex in given species. It would seem that the basis of this latter idea might be usefully incorporated in the evolution of the Manollow and similar tests. It is possible that a slight variation in the technique of the reaction in each species might give constant differential results correlated with the two pure positive sex-conditions, for the primary object of the test is the infallible determination of pure males and pure females.

#### Parental Care in the Cichlid Fishes of the Victoria Nyanza.

According to various natives from different places on the shore of the Victoria Nyanza, many of the lake fishes (all except the silurids, according to one fisherman) carry their fry in their mouths. One variation of the story makes the eggs pass internally from the ovary to the pharynx: in another the eggs or fry are gathered up from the nest in case of danger.

The account was received with almost the same caution accorded to the story of the monstrous serpent of the lake, but it has been found to apply

to several cichlids.

Eggs have been found in the mouths of Haplochromis macrodon (at Kisumu from a small native papyrus seine on Aug. 17) and H. nubilus (at Bukoba from a cast-net on Sept. 7). Newly hatched young were found in the mouth of one specimen of H. nubilus taken in a cast-net at Bukoba on Sept. 6. Two specimens each with young advanced beyond the stage of complete absorption of the yolk-sac were taken in the same manner on Sept. 6 and 7. One Tilapia variabilis taken from a large native papyrus seine at the mouth of the Kibos River near Kisumu on Aug. 14 had young in its mouth with the yolk-sac almost completely absorbed. Advanced young were taken from H. crassilabris at Kısumu on Aug. 17.

One haul with a seine on Rusinga Island at the mouth of the Kavırondo Gulf on Sept. 1 yielded 19 cichlids. Seven of these had eggs or young in their mouths. These were placed in an aquarium, and included various stages from eggs which hatched within an hour to young in which the yolk-sac was completely absorbed. The seven fish were: one Macropleurodus bicolor, five Haplochromis nubilus, and one H. ishmaeli.

On Aug. 24 one H. ishmaeli was kept alive of two taken with young in the mouth. This fish and its fry were placed in an aquarium, and towards evening it was observed that the fry had gathered up into a fairly dense shoal near the parent's mouth and their apparent number had decreased. Parent and fry died shortly afterwards.

In all cases the parent concerned was the female. The Tilapia parent and young were kept in a vessel for one week. Although the fish was not supplied with food, the young were not eaten, which is not in keeping with a theory that the fish taken with small fish in the mouth were caught in the act of eating

In several cases the mouth of the mother was packed quite full of eggs or young, so that the soft part of the lower jaw was noticeably distended.

The nomenclature used herein is after Tate Regan (Proc. Zoo. Soc., 1922). MICHAEL GRAHAM.

Fishing Survey of Lake Victoria, Kisumu, Kenya Colony, Sept. 16.

#### Application of the Interference Method to the Determination of the Surface Area of Metallic Nickel Films.

WITH the quantitative establishment of the interference theory of the production of colours on metallic copper (Proc. Roy. Soc., A, vol. 115, p. 570; 1927) and its application to the study of the sintering of reduced copper films by heat treatment (Jour. Chem. Soc., July, p. 1597; 1927) the behaviour of nickel films becomes of increasing interest. Spectrophotometric observations on the growth of oxide films on nickel showed again that interference was the primary cause of the colours developed during oxidation, and hence the same method is applicable to the study of nickel films. Moreover, the dispersion shown by nickelous oxide is very much smaller than that shown by copper oxide.

Taking advantage of the indifference of metallic mckel to carbon at low temperatures (N<sub>12</sub>C seems to be formed at 2100° C., but rapidly dissociates at lower temperatures) the nickel was electrolytically deposited on china clay coated with graphite. The nickel film was activated by oxidation in air and reduction by hydrogen at 520° C., and the conductivity of the film was plotted against the equivalent air thickness corresponding to the colour shown by the partially oxidised rod. From the slope of the straight line so obtained the surface area per unit mass may be calculated.

Let M be the mass of the nickel being oxidised, and S be its surface area,

c be the initial conductivity of the metal,

t be the thickness of the oxide film when the initial conductivity has fallen by  $\Delta c$ , and

μ be the refractive index of the oxide for middle of the absorption or reflection band in the spectrum of the film.

Then

$$\frac{S}{M}\!=\!\frac{74\cdot7}{6\ 4\times58\cdot7}\cdot\frac{\mu\cdot\Delta c}{c\cdot t}$$

For the electrolytic metal the preliminary results gave  $3.94\times10^3$  sq. cm. per gram, on activation by alternate oxidation and reduction at  $520^\circ$  C., the value fell to  $3.10\times10^3$ ; this catalyst was oxidised and reduced at  $400^\circ$  C. On re-oxidation at  $400^\circ$  C. the active portion of the surface, which oxidised very easily, had the increased area of  $1.4\times10^4$  sq. cm. per gram. The area of the supporting material was  $2.14\times10^3$  sq. cm per gram of nickel, showing that the surface of electrolytic nickel is 1.84 times the apparent area, and that the apparent surface may be increased considerably by reduction at  $400^\circ$  C.

# Thermal Degeneration of the X-ray Haloes in Liquids.

The theory of X-ray diffraction in fluids put forward some years ago by the writer with Dr. Ramanathan (Proc. Ind. Assoc. Cult. of Science, vol. 8, pp. 127-162; 1923) indicates that the diffraction halo exhibited by liquids under ordinary conditions should be strikingly modified by rise of temperature. As explained in that paper, it follows from thermodynamic considerations that at ordinary temperatures the molecules of a liquid are ordered in space with a high degree of regularity, and the comparative sharpness of the X-ray halo at such temperatures is a consequence of this fact. With rise of temperature, however, the molecules are thrown into increasing disarray, as is shown by the considerably enhanced scattering power of the liquid for ordinary light. Accordingly, we should expect the X-ray halo to become more diffuse and faint; it should also contract to some extent, owing to the diminished density and consequent increase of the mean distance between neighbouring molecules. Vice versa, if the liquid is supercooled until it congeals into a glassy solid, we should expect the halo to become sharper and brighter, and at the same time to dilate somewhat.

These consequences of the theory as well as the influence of the asymmetrical shape of the molecules on the structure of the X-ray haloes, were set out clearly in the paper, though at the time it was written no experimental evidence could be adduced in support. It is satisfactory to note that an examination of the subject undertaken by Dr. N. K. Sethi and Mr. S. S. Ramasubramanian in the writer's laboratory has shown the predicted degeneration of the diffraction halo with the rise of temperature to be an experimental fact. There is found, as expected, a progressive change of the halo from a comparatively sharp and bright ring in the amorphous solid at low temperatures to a fainter and more diffuse aureole in the liquid state at high temperatures. C. V. RAMAN.

210 Bow Bazar Street, Calcutta, Oct. 16.

No. 3030, Vol. 120]

#### Solution of the Equation $\sin \theta/\theta = c$ .

A MUCH simpler solution of the above equation than that given by Mr. V. Naylor in Nature of Oct. I may be derived by expanding the expression on the left into a series of ascending powers of  $\theta$ , and transforring the higher terms by successive approximations to the other side as terms in powers of d, where d = 1 - c. The solution so obtained is.

$$\theta = \sqrt{6(d+0) 3d^2 + 0 137d^2 + \dots}$$

This expression is so convergent that the second term does not affect the value of  $\theta$  by half a second for values of  $\theta$  up to 2°·6, the third up to 15°, and higher terms only affect the result for angles more than 30°. For small angles, or for a fair approximation with larger angles, we may simply write the solution  $\theta = \sqrt{6d}$ , or for  $\theta$  in degrees, 140° 345  $\sqrt{d}$ . It c be very near unity, the complement has fewer significant figures than the reciprocal, while the terms in  $d^2$  and  $d^3$ , when required, are so small that they can be worked by slide rule or three- or four- figure logarithms for adding to d. E. Levin.

#### Viscosity of Metals: Bismuth.

SINCE publishing the concluding part of my investigations on the viscosities of metals ( $Phil.\ Mag.$ , April 1927, Supp.) I have come across the following data for bismuth—a metal I could not procure in the form of a wire. In an attempt to study, for a different purpose, the elastic properties of pure bismuth wires prepared from electrolytically deposited metal, J. E. Harris ( $Phys.\ Rev.$ , First Series, 35, pp. 95-119) tabulated the values of log. dee for different amplitudes for a wire of length 106 cm.; diam., 0.25 mm.; period, 10-498 sec.; moment of inertia of the solid, 133 gm. cm.²; which on extrapolating for zero amplitude give  $\lambda_0 = 0.00978$ . These results give for the coefficient of viscosity of bismuth, at 23°.7 C.,  $13.71 \times 10^8$  poises—a value quite in a line with others obtained by me with thirteen metals and seven alloys.

As these experiments were not conducted in an airfree chamber the above result for bismuth is, however, likely to be slightly higher.

# The Temperature Variation of the Elasticity of Rochelle Salt.

Mr. R. Morgan Davies's letter on this subject in Nature of Sept. 3, recalls at once the analogy between piezo-electric phenomena and the reciprocal relations between strain and magnetic properties shown by ferromagnetic metals.

In particular, there is a stationary value in the Young's modulus—temperature curve for nickel at about 400° C., the Curie point for that material (*Proc. Phys. Soc.*, London, vol. 27, Dec. 15, 1914).

(Proc. Phys. Soc., London, vol. 27, Dec. 15, 1914).

A close examination of the temperature variation of the thermal expansion of a piezo-electric crystal would be expected to reveal a discontinuity at the temperature of abrupt change in the piezo-electric modulus which, if present, would be analogous to that found by the writer in the thermal expansion of nickel (Phil. Mag., June 1904), and confirmed by Colby (Phys. Rev., 30, pp. 506-521; April 1910).

H.M.S. Vernon, Portsmouth, Oct. 19.

# The Empire Mining and Metallurgical Congress in Canada.1

AT the Second (Triennial) Empire Mining and Metallurgical Congress, opened on Aug. 20, at Montreal, then continued across Canada to the Pacific, and eventually ended at Quebec on Sept 26, the underlying motif was the question of mineral resources.

At the opening session a resolution that the question of a review of the mineral resources and industries of each administrative unit throughout the Empire be transmitted for consideration and report, respectively, to the individual societies represented on the Empire Council, was adopted unanimously, after discussion and support by representatives from Australia, South Africa, India, the Crown Colonies, and the home country; while at the final meeting of that Council at Quebec a recommendation was adopted that for the coordination of such reports the Council should appeal for financial support and then set up an executive commensurate with the support forthcoming.

Canada, which through its governments and its mining industries had so largely borne the expense of organising this Congress, contributed to the question an exposition and display of her own wonderful mineral resources. Abundant brochures and booklets had been prepared and were distributed by the Department of Mines, the development department of the Canadian Pacific Railway, and the Canadian banks In these the position was presented that the present mineral resources of Canada were responsible for that country standing third among the nations of the world, and second within the Empire, as a producer of gold; for Canada supplying something like ninety per cent. of the world's nickel, seventy-five per cent. of the asbestos; and something like ten per cent respectively of the world's lead and zinc; and if the British Empire produced but a small percentage of the world's copper, Canada at least was the greatest producer and possessed the greatest copper mine within the All this with but half a per cent. of the world's population!

Present production is, of course, not necessarily a safe guide to mineral resources, these depending upon the unworked reserves. But the rapid rate of increase in Canada's mineral production, instanced by an increase from a value of sixteen million sterling in 1906 to fifty million sterling in 1926, is sufficient evidence that the extent to which the resources have hitherto been depleted by production has been more than made good, as we know it has, by both flattering developments of the known deposits and by new discoveries. Canada, indeed, has this century been the country of new discoveries: the silver field at Cobalt, Ontario, was discovered in 1902; the goldfield at Porcupine, Ontario, now containing the second largest gold mine in the world, in 1906; the relatively richer Kirkland Lake goldfield, Ontario, in 1912; while the promising gold-copper deposits at Rouyn, Quebec, were discovered in the present decade. It

 $^{1}$  The constitution and  $\it raison~d'\it etre$  of this Congress were outlined in Naturn of Aug 13.

is therefore safe to say that Canada's mineral production and reserves will continue to increase, and that where exhaustion may loom in some older mineral countries, buoyancy reigns in this country of all variety of geological formation and all vastness of unexplored extent.

All the foregoing districts were visited, and in addition such older established fields as the Sudbury copper-nickel field, Ontario; the asbestos areas at Thetford and Black Lake, Quebec; the Sullivan lead-zinc mine, the Britannia copper mill and the Mountain-Copper mine, British Columbia; the Saskatchewan lignites; and the Alberta coalfields. For lack of time the important Portland Canal district in north-west British Columbia, and other less important districts, could not be visited. Everywhere opportunity was provided to observe geolological occurrence, mining method, mechanical treatment, and metallurgical treatment; and in the end the visitors had a good general idea of the importance and outlook of each district.

Structural geology and regional petrography being all-important in the consideration of mineral deposits, no proper appreciation of the mineral resources of Canada is possible without some knowledge of the great natural petrographic provinces into which the Dominion may be divided. There is first the great pre-Cambrian area of hard ice-levelled outcrops which, sweeping widely around Hudson Bay, embraces entire Quebec; Ontario in far greatest part, crossing into the United States; the northern three-quarters of Manitoba and the northern half of Saskatchewan; the north-eastern corner of Alberta; a large portion of the North-West Territories, and altogether more than onehalf the superficies of Canada. In this ancient country-rock, otherwise sterile and forbidding, and within the relatively small area explored, occur among others the productive Sudbury, Cobalt, Porcupine, Rouyn, and Flin-Flon deposits, that is to say, deposits respectively of copper-nickel, silver, gold, gold-copper, and copper-zinc. In this area also, in addition to the smelters in the Sudbury district, are the Port Colborne refinery on Lake Ontario, the smelter and refinery at Deloro, and the Hamilton Works of the Steel Company of Canada.

Next in mineral importance comes the Pacific Highland of British Columbia embracing the Rockies and the Coast Ranges, where tilted and folded sedimentaries ranging from pre-Cambrian to Tertiary, alternate with intrusives and volcanics. In this scenic realm occur among others the Premier gold-silver mine and the Hidden Creek copper mine to the north-west, the Britannia copper mine on the Howe Sound to the south, and the Sullivan leadzinc mine in the Boundary District. Here also are the famous Trail smelter and refinery and the Anyox smelter. Between these two great metalliferous provinces come the Great Plains which, embracing the remainder of Manitoba, Saskatchewan, and Alberta, certain coal and lignite, oil and bituminous sand, building stone and other non-metalliferous minerals, representing a mineral wealth and reserve second only to the riches of their fertile soil. Finally, to the east come two smaller divisions, the Atlantic Provinces and the St. Lawrence Lowlands, where occur asbestos, coal, oil, shales, gypsum, and other non-metalliferous minerals.

Physiographically, half of great Canada is rocky, one quarter is covered by thick and valuable forests, somewhat less than a quarter by rich fertile soil, while the remainder is occupied by lakes or buried under moss. The agricultural and lumber industries take precedence of the mineral industry, both in their greater value and in their longer establishment. The mineral industry, started later, now challenges this precedence and, making valuable the rocky and inhospitable places of the Dominion, has earned the sympathetic consideration of the Government.

In the matter of prospecting this consideration almost becomes co-operation. The mineral discoveries in the past have largely been fortuitous and in Ontario largely in process of railway construction. But to-day geology helps. Dominion and Provincial geologists are early in the field anxious and ready to point the way to areas where rocks and structural conditions are favourable to discovery in new fields or to recurrence in known fields. Indicative of the importance which the Government attaches to the geological study of mineral deposits, Dominion geologists accompanied the Congress throughout, while Provincial geologists were detailed to be of service in their particular areas. Instrumental or geophysical prospecting plays little part, dependence being placed upon the close observation of surface indications and the intensive examination of available exposures.

All types of ore deposit are represented, some here, others there, magnetic segregations, replacements, fissure fillings, disseminations, steep lodes, flat beds, stepped lenses, irregular masses. There are also all variations in relation to dependence on proximity to the surface, from pronounced secondary enrichment as in the upper levels of the Premier gold-silver mine in British Columbia, to absence of all signs of secondary enrichment as in the pre-Cambrian area, where any such effect of weathering has long since been removed by glaciation. Surface discoveries in this latter area have accordingly this greater importance that they represent primary ore which is as likely to increase in value with departure from the point of discovery as to decrease, and in general character is not likely to vary. They have also this further importance that being in rock which, though now at the surface, was nevertheless under pressure of depth at the time of their formation, further development in depth is as likely to disclose an increase in size as a decrease, no further consolidation having to be expected. In this area it has been the repeated experience that the surface or shallow indications did not do justice to the value and size afterwards disclosed; indeed some valuable ore bodies developed underground were not even represented at the surface.

In the testing and development of discoveries, not only do shaft sinking and tunnel driving proceed apace, but diamond drilling even more so.

So flattering have recent developments been on particular discoveries that early results are everywhere now regarded as an urgent necessity, as witness the fact that recently a diamond drill was despatched to a prospect in Central Manitoba by aeroplane. Nor does such drilling necessarily slacken when a sufficient mining equipment is functioning and underground levels and roads are rapidly opening out; at appointed intervals to right and left and underneath the drill keeps in advance, defining the limits of the known ore-bodies and probing for others. In this way mineral reserves become indicated before being actually developed and a proper scale of operations is projected at an earlier date.

With regard to mining methods, Canadian mining is not yet very deep, the deepest shaft being one just over 4000 feet in the Porcupine district; nor by reason of many workings close together have special methods had to be devised to meet the pressure of heavy ground; standard methods are in use everywhere Shaft mines are represented by general practice in the pre-Cambrian area where the deposits stand steeply and where sufficient mass can rarely be recovered from open pits; they are represented also in the shallow coal and lignite fields of the Great Plains. Tunnel mines worked from the hillside are the feature of the Pacific Highlands. Among these, deserving of especial mention is the Sullivan lead-zinc mine in the Boundary district which works a flatly inclined massive sulphide bed, in places of immense size. Here the present mining method is to support the roof, leaving regular mineral pillars, the intervening excavations being as large as the strength and solidity of the roof allows. Actually some of the resultant excavations are so large that their limits could only be made visible by searchlights, and climbing within them from one level to another gave at times the impression of mountain climbing at night. In these Highlands and adjacent country the coal seams, being contorted and folded, are worked from the hillside. Openpit mining is represented by the asbestos mines in Quebec, where the pits, and equally the resultant dumps, are of staggering proportions; by the Copper Mountain mine in south-east British Columbia; and by the mining of some thick and shallow coal beds in

In the beneficiation of the material mined, that is, in the milling processes preparatory to metallurgical treatment and in the metallurgical processes themselves, Canada has much to show.

Alberta.

In milling practice most impressive and convincing was the separation by differential flotation of lead and zinc sulphides from one another, and both from the worthless portion of the complex fine-grained ore at the Sullivan mine With the first successful introduction of the flotation process in 1910, this property, which had been lying in abeyance for lack of any suitable treatment, became once again of interest, now, with the further development of that process to differentiate between sulphide and sulphide, it has become one of the most profitable lead-zine mines in the world.

The mill there is a triumph of applied science Arriving at the mill head, the ore is mechanically crushed, conveyed, weighed, sampled, and ground to pulp with water. This pulp is then churned and infused with air, while reagents are added. These reagents, though added in such infinitesimal quantity as only to contaminate, are of such potency that when the first is added the lead sulphide floats in the resultant froth, and the zinc sulphide afterwards with the second, the stony Broken down material sinking to be discarded with water these froths separately are settled and filtered, the relatively dry sulphides dropping on to conveyors to be carried to railroad wagons waiting at the tail end, sampling taking place on the way. Hundreds of tons a day of each sulphide and a thousand tons together are thus recovered, with no man handling the material.

Scarcely less fascinating but not so modern is the recovery of asbestos fibre from its serpentine matrix. First comes again the effective release of the valuable material by appropriate comminution, the last stage being here by an impact blow in air. The effect of this communution is that while the serpentine is reduced to granular powder the asbestos fibre is teased into light fluffy masses. Passing this mixture under stationary vacuum cleaners the fluffy asbestos is sucked up and away while the worthless granular material passes on, eventually to reach the dump waste.

Pure metallurgical practice in Canada is even more impressive. Pyrometallurgy is represented by roasting, matte-smelting, and converting, in the well-established production of nickel metal and matte and blister copper at Sudbury, Ontario; in the grand-scale beneficiation of lead and copper at Trail, British Columbia; and in the hopeful erection stage for the production of gold-copper matte at Rouyn, Quebec. Fire also effects the final melting and casting of fascinating yellow gold at Porcupine; of shining white silver at Cobalt; of resplendent red copper, of dull white lead, and of crystalline white zinc at Trail; and of hard white nickel at Sudbury.

It is nevertheless in electro-metallurgy that Canada secures pride of place, taking advantage of abundant current generated by cheap water power. At the Trail smelter, fire for roasting, solvents for dissolving, current for deposition, and fire again for melting, is the sequence by which 280 tons of refined zinc bars are produced each day, the only other comparable electrolytic zinc plants in the world being at Great Falls, Montana, and at Risdon, Tasmania, these being smaller. Here also 400 tons of electrolytically refined lead and 60 tons of refined copper are produced daily, together with about 20,000 ounces of silver and 100 ounces of gold gathered from the electrolytic cells. The long extended halls in which the thousands of depositing boxes necessary for these tonnages are accommodated are impressive in their immense size and in their attendant equipment, travelling cranes sweeping overhead to bring in the heavy anodes and to withdraw the loaded cathodes, and ground trams for the transport of lighter units.

At Trail, in the production of the refined tonnages mentioned above, all modern metallurgical operations and all modern metallurgical appliances are represented, and the whole complex becomes the largest non-ferrous metallurgical works in the world, electrolytic refining being its special feature.

Hydro-metallurgy is represented at Porcupine and at Kırkland Lake, more purely perhaps in the latter district. There is nothing new in the procedure. But the ordered design and simple lay-out manifest the assurance which came from knowledge of the problem Dull, unmetersing-looking ore enters at one corner of the building while fascinating gold bars leave at a far corner, with no apparent connexion between the two. But there it was, the trained man's capacity and intelligence!

The heart of one and all of these vigorous mineral enterprises is at the office and laboratory. The knowledge of which use is made comes from all over the world. Mineral resources are not to be measured only in terms of the earth's physical endowment, but also in terms of the vigor and intelligence with which they are sought and turned to account. In this matter Canada is worthy of her sons, while they in turn are blessed in her mineral fertility.

The Empire as a unit produces something like a quarter of the world's mineral output, lacking in but few mineral or metal commodities. The mother country of itself contributes practically nothing to the output of the non-ferrous major base metals, or to that of the precious metals. Yet in her sons, by research, experiment, and invention, she has contributed worthily, to wit: the Bessemer process which, originally revolutionising steel making, is now an important factor in the beneficiation of copper, nickel, and associated precious metals; the Macarthur-Forrest cyanide process for the recovery of gold and silver, which revolutionised precious metal mining, and, finally, the impulse through Elmore, Sulman, Picard, and others, to the present perfection of the flotation process by which the base metal mining industry has been equally revolutionised and mankind benefited.

A further contribution of the mother country to the mineral industry has been that of capital. In South Africa, Australia, India, and in Canada, British capital from the mother country has been of use, in large measure profitably to those supplying it. It is Canada's hope that one result of this Congress may be that more of such British capital may be forthcoming for the development of her resources, to the particular advantage of those venturing it and to the advantage of the Empire as a whole. Capital is particularly wanted for the initial stages, the testing and development of discoveries. British capitalists considering to take an interest in Canadian mining must accept the position that Canadians believe in, and by recent experience are justified in believing in, the great mineral possibilities of their country, and that they apply this belief to each individual mine and discovery; boldness with discrimination is therefore required. On the other hand, such capitalists may assure themselves that the Canadian public is itself willing and anxious to share in mining risks. The government is good and stable, and sympathetic to pioneer effort, readily making roads and railroads. The country abounds in cheap power, in water, and in timber, and labour is plentiful and efficient.

The Canadian mineral industry will continue to develop Capital will be attracted, and the desire of Canadians that more of that capital shall be British is both real and honest, springing from the fact that, sharing them, they admire British ideals and British institutions, and highly value the British connexion. Though much has been done in opening out Canada, Canadians realise that much more remains to be done and some things to improve, and they would have this further development conducted so far as possible in harmony with British ideals.

On their side the British visitors, from wherever they came, were moved by the warmth of their reception everywhere, and stirred to admiration by the monuments of Canadian construction and

enterprise. In the fellow-feeling and confidence therefrom engendered lies the gain to Canada. The gain to the visitors lies in having seen what has been accomplished in Canada

Lest it should appear that the Imperial note has been stressed unduly, the following concluding paragraph of the report on the Congress by the representative of the Engineering and Mining Journal of New York may be quoted. "I was not part of the Congress-merely an onlooker, a correspondent, reporting what I saw and heard. I am not even British, and this has been a British party. Nevertheless I was accorded every privilege and every consideration, wherever we went. Collectively, and individually, I have never seen a more interesting, sociable, and friendly group of people. Possibly one reason for this is the fact that mining is distinetly a world-wide industry and that mining people have much in common no matter whence they come; but behind that is probably the simple fact that they are British." S. J. TRUSCOTT.

# Directional Wireless as an Aid to Navigation.

By Dr. R. L. SMITH-ROSE.

FTER several years of struggle with a rather conservative race of navigators, the wireless engineer and scientist are becoming successful in the application of directive wireless transmission or reception to both aerial and marine navigation; and it can now be said with some confidence that in a very few years time the wireless directionfinder, or some alternative means of navigation by wireless, will be considered as essential as a compass on board every ship of any importance. Already a considerable number of ships of all nationalities, with those of Great Britain leading the way, are fitted with a direction-finder, an instrument which enables a ship to take bearings on wireless transmitting stations and to fix its position with some accuracy at times when all other navigational methods fail.

The application of wireless transmission as an aid to navigation is conveniently divisible into two parts according as the directive characteristic is applied at the transmitting or the receiving end of the wireless link. Although both forms are probably of about the same age, the directive receiver has developed the more rapidly and will thus be considered first.

# THE DIRECTIONAL RECEIVER OR DIRECTION-FINDER.

Stated briefly, the fundamental principle of the wireless direction-finder is the rotation about a vertical axis of a plane vertical loop or its equivalent in space. The electro-motive force induced in such a loop by an arriving stream of electro-magnetic waves is proportional to the cosine of the angle between the plane of the loop and the direction of the waves. Thus as the loop is rotated about its vertical axis the strength of the received signal varies from a maximum to a minimum or zero, in accordance with the well-known figure-of-

eight polar diagram. A consideration of this diagram shows that the rate of change of signal strength with rotation is greatest at the minimum position, which is therefore always used for direction-finding.

(a) Accuracy of the Direction-finder.—There are several manufactured forms of direction-finder employing the above principle, and their accuracy when used under the best conditions may be said to be about 1°. Under most practical conditions, however, the instrument is subject to certain errors in determining the direction of a distant transmitter. In part these errors may be due to an actual deviation of the waves from their rectilinear path in crossing a coastal boundary, for example, when a maximum deviation of about 5° may be produced for wave-lengths of the order commonly used in marine direction-finding. On the other hand, the errors may arise from the presence of local conditions near the directionfinder, such as trees, metalwork, and overhead wires, the currents induced in which result in secondary fields being superimposed on the primary wave field and so produce a minimum signal in a false position of the direction-finder. As a result of several years' investigation these errors are now well understood, and in most circumstances they may be avoided or compensated for after reduction to a minimum.

(b) Position of the Direction-finder.—In the application of direction-finding to marine navigation, a point of some debate has been the most desirable location for the instrument, on shore or on board ship. When erected in suitable surroundings, the shore direction-finder has an accuracy superior to that of the ship installation, for in the latter case the wireless bearing is taken relative to the ship, and reference must be made to the compass in order to determine the orientation of the

No. 3030, Vol. 1201

ship at the instant the bearing was taken Moreover, the ship direction-finder is subject to a local error of a quadrantal nature due to the currents induced by the arriving waves in the metalwork, hull, stays, etc., comprising the ship itself. On the other hand, it is natural to find that the average ship's navigator does not care to entrust himself to the observations of an individual on shore with whom he is not in personal touch, and particularly at critical times in stormy or foggy weather, he much prefers to have the instrument on board ship and operated under his immediate control.

Furthermore, the ship fitted with a direction-finder is enabled to take bearings upon the transmissions from other ships; and at least one instance can be quoted in which a ship in distress, after signalling its inaccurately estimated position, has been found at a position one hundred miles away by means of a direction-finder on the rescuing ship. A possible future development of the ship direction-finder is the provision of a safeguard against

collisions at sea in times of thick fog

(c) Conditions for Freedom from Night Errors.— It is now well known that wireless direction-finders, even in the most favourable situations, are subject to a variable error under certain conditions of transmission, which chiefly occur at night. These errors are due to the reception of waves deflected in the upper atmosphere, which therefore arrive at the direction-finder travelling in a downward direction So long as these waves are polarised with their electric force in the vertical plane of propagation, the true bearing will be read off on the direction-finder But if, as is frequently the case, the plane of polarisation of these waves is rotated, then the resultant magnetic field produced at the earth's surface will not be perpendicular to the plane of propagation and an apparent error will be recorded on the instrument.

The actual value of the error will depend upon the relative magnitude of the down-coming waves and the waves transmitted directly along the earth's surface, since it is determined by the direction of the resultant magnetic field due to both sets of waves Close to the transmitter the ground wave predominates and no error is produced. At a distance of about 30 miles overland, the strength of the ground wave has become reduced, and the angle of incidence and relative strength of the downcoming wave have increased sufficiently to introduce an appreciable error in bearing at night. Fortunately for marine navigation, however, the attenuation of the ground wave is much less when travelling oversea, and the downcoming wave does not become effective until the distance from the transmitter is about 80 miles Thus when, as is usually the case, the ship's direction-finder is operated on transmissions which are entirely across the open sea, the bearings are equally trustworthy by day or night up to distances of 80 to 100 miles.

#### FIXED BEACON STATIONS.

Concurrently with the development of the radio direction-finder on board ship, the United States

lighthouse authorities have proceeded with the establishment of radio beacons, or fixed transmitting stations which send certain code signals automatically when once set in operation. number of these stations are already working, and others are proposed or in course of erection. The majority are located on light vessels or near shore lighthouses in the vicinity of the chief harbour entrances, but others are situated on the Great Lakes in the north of the United States. Each station has a characteristic signal easily recognised by an untrained ear and distinctive from any other in the vicinity, and all the stations are clearly marked on charts at points well known to navigators, so that a radio bearing can be definitely identified and plotted on a chart with the same facility as a visual bearing.

It is interesting to note that while the number of British ships fitted with direction-finders is considerably greater than that of any other country, there was, until recently, no fixed radio beacon in the British Isles officially working for the use of these ships. Quite recently, however, the first of a general scheme of fourteen wireless beacons has been erected at Round Island, in the Scilly Islands, by the Trinity House authorities Other beacons are in course of construction at Lundy Island and the Casquets. The Round Island beacon, now in operation, is situated near the lighthouse and employs a simple valve transmitter of moderate power working to an ordinary open aerial. The running of the station is entirely automatic, even to the replacement of the transmitting valves in case of failure; and the installation is maintained in working order by the staff of the lighthouse.

### DIRECTIONAL TRANSMISSION.

(a) The Beam System.—In recent years the arrangement of groups of antennæ and reflector wires to give a concentrated beam of radiation has been developed to a considerable extent and is now coming into extended use for long-distance communication. If such a beam is made to revolve about a vertical axis, the device becomes analogous to a lighthouse, and signals are detectable at a distance only as the beam flashes past the receiver. By arranging a code of signals in such a way that they are transmitted automatically in succession as the radiating system rotates, then a vessel at sea would, in any position, receive a distinctive signal from which its bearing from the transmitter can be immediately ascertained. In order that such a scheme may be realised in practice, it is necessary that the dimensions of the aerial and reflector system shall be made reasonably small, which implies that the wave-length is correspondingly short. Up to the present, two stations have been equipped with such rotating beam transmitters; the first at Inchkeith, in which a parabolic reflector was used, and the second at the South Foreland, at which the antenna and reflector systems were in the form of plane grids or curtains. The wave-length employed was in the neighbourhood of six metres, and the limited range obtainable, together with the necessity of providing special short-wave receivers on those ships using the device, have probably accounted for the un-

popularity of the system

(b) Rotating Loops. — An alternative method of directional transmission is to invert the directionfinder, and set up a closed loop or frame-coil, supplied with oscillatory current from a suitable transmitter. If the loop be rotated uniformly about a vertical axis, then the signal obtained at a distant receiver will vary according to a cosine law, passing through a zero or minimum when the plane of the loop is perpendicular to the direction of transmission. The orientation of the loop at this minimum signal position can most easily be deter-A characteristic mined by a timing method. signal is emitted when the minimum radiation from the loop is in either the north or east direction, and by measuring the time interval between the reception of this signal and the passage of the signal through its minimum intensity, the bearing of a distant receiver from the transmitter can be easily obtained. Other and somewhat more complicated methods of deducing the bearing have been suggested, and consist in imparting to the radiation some characteristic which depends upon the orientation of the loop; for example, the wavelength may be varied continuously during rotation.

The rotating loop transmitter used with a timing method has been developed to a high degree in Great Britain by the Air Ministry, and its applicability to marine working is now under investigation. The method has considerable attractions, in that it can be operated on the wave-lengths usually employed in ship and aircraft communication, and in merely requiring at the receiving end a suitable watch and the ordinary type of wireless receiver. A further advantage hes in the fact that the directional part of the system is located in a fixed

position on the ground, and that the observed bearings are independent of the direction in which the ship or aircraft is pointing, and are almost entirely immune from any disturbing conditions local to the receiver. It is therefore likely that this method will play an important part in the future of navigation wireless.

(c) Course Setters.—In concluding this survey, brief mention may be made of the so-called wireless course setter The use of the directional transmitter has considerable advantages for the navigation of aircraft in that it can be installed at the home station, and the aeroplane has then merely to fly on a constant bearing line to arrive at its destination. To assist in this object an arrangement of a pair of loop transmitters was devised some years ago in Germany, the loops being identical and fixed together at some convenient angle. The loops may either be excited alternately at intervals of once a second, or they may be excited together, but each loop is arranged to emit a Morse signal which is complementary to that

given by the other

When the receiver is located on a line bisecting the angle between the loops, both signals will be received of equal intensity and will thus be indistinguishable from each other. On either side of these bisecting lines the signal from one loop will predominate over that from the other. while such a scheme is only available over definite courses or air routes, it has the advantage over other directional methods in requiring no special apparatus or timing arrangements, and it gives an immediate indication of any departure from the course caused by drift from wind or tide. Such a method has received considerable attention in America, where it is proposed to establish a network of wireless beacons along the main civil aviation routes.

# Obituary.

#### SIR WILLIAM GALLOWAY.

THE death of Sir William Galloway, which occurred at his home in Cardiff on Nov. 2, removes an outstanding figure in the development of scientific coal-mining. Galloway made a number of important contributions to methods of coal-mining, but he will chiefly be remembered as the originator of the theory, now everywhere accepted, that the great explosions which used, in the absence of proper precautions, to sweep through the roads and workings of collieries, are due to the combustion of coal-dust raised into the air.

Galloway was born in 1840, and belonged to a well-known family associated in the west of Scotland with coal-mining and engineering enterprises. After studying at Giessen, and later at University College, London, he became a junior Inspector of Mmes, first in Scotland, and afterwards in South Wales. His attention was thus directed to the causes of explosions He soon saw that the theory then everywhere accepted, that the great explosions are propagated by the combustion of

fire-damp, was quite incapable of explaining the actual facts; and in a series of papers published in the *Proceedings of the Royal Society* between 1875 and 1887, he formulated and supported the coaldust theory. His conclusions were derived mainly from an analysis of the evidence afforded by actual explosions, and the demonstration from this that fire-damp could not have been present in appreciable proportion along most of the track of each explosion. The rest of his evidence consisted in the results of experiments on the surface in a gallery constructed for the purpose at a South Wales colliery controlled by his friend and countryman, Mr. A. Hood.

At first Galloway was only able to obtain ignition of a coal-dust cloud when about 1 per cent. of firedamp was present in the air, but later he succeeded without the addition of fire-damp. The gallery was too short for the development of the extreme violence often displayed in underground explosions, and it was only in the long experimental gallery built in 1905 at Altoft's Colliery under Sir William Garforth's supervision by the Coal

Owners' Association, that a coal-dust explosion was obtained of sufficient violence to blow the gallery to pieces, and hurl masses of the boiler-plate of which it was constructed five hundred feet into the air.

For many years Galloway's conclusions were received with almost universal scepticism. The idea that colliery explosions are simply due to firedamp was firmly rooted. It was, moreover, known that blasting with ordinary gunpowder was commonly carried out with impunity at working faces, provided that fire-damp was absent, though much coal-dust might be present. Owing to the conflict between his views and those of senior colleagues, he had to resign his position as inspector of mines. Gradually, however, confirmation came from other mining engineers or scientific investigators, and particularly from junior inspectors of mines, among whom the brothers W. N. and J. B. Atkinson and Mr. Henry Hall took a leading part. Meanwhile, Galloway held for many years the chair of mining at University College, Cardiff. He also became a well-known consulting mining engineer, and remained so until his death, retaining his activities and scientific interests to the last.

Galloway never tired of urging the necessity of precautions against coal-dust explosions. He laid most stress on keeping the roads wet, and providing dust-proof underground waggons; but he also pointed out, and proved by experiment, that the dust could be made safe by the addition to it of inert material. The latter precaution, independently initiated and vigorously developed by the late Sir William Garforth, has turned out to be practicable and effective; and our knowledge of the conditions under which coal-dust explosions occur, and what is necessary to prevent them, has advanced rapidly in recent years, a great part of the advance being due to the experiments carried

out under Prof. Wheeler's supervision at the Experimental Stations at Eskmeals, and later at Buxton.

The death-rate from colliery explosions in Great Britain has been reduced to about a tenth of what it was when Galloway began his work. No better tribute than this could be paid to the inherent value of that work, since it is the attention which has been paid to the dangers from coal-dust that has brought about the reduction. But even if he had turned out to be wrong about coal-dust, those who knew him would still have loved and respected him for the greatness of his character. J. S. H.

THE memorial address on Prof. O. Wiener delivered by Prof. L. Weickmann before the Academy of Science at Leipzig on July 1 is reproduced in the Berichte of the Academy for that date. Otto Wiener, the son of Christian Wiener, professor of mathematics in Karlsruhe, was born on June 15, 1862, and after leaving school became a student in Karlsruhe, Berlin, and Strasbourg in succession. At Strasbourg he was associated with Kundt, and obtained his doctorate in 1887 with a thesis on the measurement of the thickness of the thin metallic films used by Kundt in his work on the passage of light through metals After acting as assistant in Strasbourg and in Aix-la-Chapelle, Wiener was appointed professor at the latter in 1894, and at Glessen in 1895. After building a new physics institute there, he was appointed to Leipzig in 1899 and built a still larger institute, which was opened in 1905. He had much to do with the establishment of aeronautical and meteorological departments at Leipzig, and more recently was engaged in developing a kinetic ether theory of the universe. He is, however, best known for his optical researches. He died on Jan. 18 last.

#### News and Views.

On Tuesday, Nov 15, M. Paul Pamlevé, professor of celestial mechanics at the Sorbonne, and French Minister for War, gave an evening discourse at the Royal Institution before a large audience M. Painlevé's lecture took the form of a general review of the evolution of scientific conceptions on the structure of matter from the early speculations of Greek philosophers down to the most recent and advanced theories. He pointed out that this problem resides essentially in a change of scale, and put the question as to whether matter would appear continuous or discontinuous if our senses were refined far beyond the range of our most powerful instrument—the famous controversy of plenum versus vacuum turn, continuity and discontinuity have seemed to prevail as an explanation of matter and of light. The atomic theory, and the corpuscular emission of light on one hand, and on the other hand thermodynamics and the theory of luminous waves, are characteristic of these two tendencies. Turning to the question of the reality of molecules, M. Painlevé referred to the great number of very diverse methods agreeing to a remarkable degree of accuracy in their result as to the number of molecules in a unit weight, and mentioned in this connexion the researches of Prof. Perrin on the Brownian movement. He then dealt with the atomic microcosm, showing that the study of corpuscular radiations forces us to introduce the idea of discontinuity inside the atom and to regard all matter as made up of two final elements onlythe electron and the proton. Towards the end of the lecture, M. Painlevé mentioned the difficulties which he in the way of explaining the luminous spectra emitted by atoms, and expressed the hope that the new mechanics, by associating material corpuscles with these mysterious waves, would ultimately overcome those difficulties. He showed a series of interesting slides illustrating points which he had discussed in his lecture, such as atomic impacts and coloured regions with well-marked outlines indicating differences of molecular thickness in soap films. The audience frequently expressed appreciation of the lecturer's eloquent exposition of his subject.

On Thursday, Nov. 17, M Paul Pamlevé lectured at the Institut Français du Royaume-Uni in Cromwell Gardens, South Kensington, on "Absolu et Relativité," under the charmanship of Lord Askwith, chairman of the Council of the Institut. M. Painlevé emphasised the essentially scientific character of the theory of relativity, which has often been falsely represented as a metaphysical doctrine. He considered it important to distinguish carefully between the scientific theory of relativity and the "transcendental subjectivism, which assumes that our sensations alone are a fact, a reality, and that the universe is nothing but an illusion" Relativity demands the objective reality of the external world. What it does is to deprive time and space of the absolute character with which they have previously been wrongly endowed. They are so closely interconnected in our perception of the universe that we can not realise the absolute except as a combination of them. M. Painlevé went on to discuss the definitions of time and space measures in relation to the principle of casuality, and showed that it is necessary for the relativist to regard the notion of simultaneity of events occurring at different places as a partially relative one. The principle of relativity has introduced simplifications into the electro-magnetic interpretation of Fresnel's optics, but these simplifications require the assumption of a time system special to each observer. This requirement has given pause to many would-be adherents of the theory, while others have thought to find an essential contradiction in the theory. In M. Pamlevé's opmion, the theory is coherent and logically sound. Einstein has given us a view of the universe which entails a revision of the fundamental principles of science but strengthens them enormously.

The Council of the Royal Meteorological Society has awarded the Symons Memorial Gold Medal for 1928 to Prof. Hugo Hergesell, Director of the Aeronautical Observatory, Lindenberg, for distinguished work in connexion with meteorological science medal, which is awarded biennially, will be presented at the annual general meeting on Jan. 18, 1928. Prof. Hergesell has for many years played a prominent part in the development of meteorology. So far back as 1896 he was chosen as president of the International Commission for Scientific Aeronautics; and that Commission continued to organise upper air observations until the outbreak of the War. The data from 1900 to 1913 were published by Hergesell at Strasbourg, and he supplemented the work done there by ascents in widespread regions over the oceans. In 1914 he succeeded Assmann as Director of the Aeronautical Observatory at Lindenberg, which issues the daily weather reports of the upper air for the use of pilots over a large region  $\cdot$  there he has shown very great organising ability, as is indicated by the scientific output of that institution. It has made and published an enormous mass of upper air observations, and has digested and discussed these in an admirable manner. Not only has the Director himself made important contributions to knowledge, but he has also

trained a number of men some of whom have made world-wide reputations by advances of meteorological science. Prof. Hergesell is also editor of the *Beitrage* zur Physik der freien Atmosphare, which he founded with Dr. Assmann

When Prof. J. A. Fleming retired from the chair of electrical engineering at University College, London, which he held for forty-two years, a committee was formed under the chairmanship of Mr. A. A. Campbell Swinton, to present University College with an oil portrait of Prof. Floring, and also to present Prof. Fleming himself with a copy of that portrait. The committee, a very representative one, was fortunate in getting the portrait painted by Sir William Orpen, a former art student at the Slade School, University College. Sir William Orpen also arranged for a copy to be made which the committee intended for Prof. Fleming, who, however, has decided to present it to the Institution of Electrical Engineers. The original will be presented to University College by the committee on Wednesday, Nov. 30, at 5 P.M., and the copy will be presented to the Institution by Prof. Fleming on Thursday, Dec. 1, at 6 P.M., at the ordinary general meeting of the Institution to be held on that

THE amalgamation of the Rontgen Society with the British Institute of Radiology was formally completed at a joint general meeting of members of the two Societies on Nov. 17. Sir Humphry Rolleston was elected president for the ensuing session, with Sir William Bragg, Dr. Kaye, and Dr. Knox as vicepresidents. The president, in his maugural address, referred to the history of the two constituent bodies. and sketched the possibilities of the widened scope of activity which should follow the amalgamation This scope was exemplified in the following day's meetings. In the morning, papers were read on X-ray and radium protection by Dr. Kaye; and on X-ray measurements, by Prof. Crowther, Prof. Hopwood, Prof. Owen, Mr. C. E. S. Phillips, and Prof. Russ. In the afternoon, papers were read on the use of opaque injections as an aid to X-ray diagnosis; Sir J. Purves-Stewart dealing with the nervous system, Sir J. Thomson-Walker with the urmary system, Dr. Burrell with chest conditions, and Dr. Gibbons with gynæcological conditions. The Rontgen Society and the medical society, formerly known as the B.A.R.P, have each contributed much in the past to the progress of the study of radiology and of the application of X-rays and radium in medical practice, their united efforts should secure a mutual acceleration of effect, and it is to be hoped that the result of the amalgamation will be to enhance the status and value of British radiology in all its branches.

The presidential address of Prof. C. H. Desch to the Sheffield Society of Engmeers and Metallurgists, recently issued by the Society, is of unusual type, in that it concerns itself less with technicalities of science than with the geographical and social relations of Sheffield's industry. The treatment shows Prof. Desch's well-known breadth of knowledge and of

understanding. Without pure ores close at hand, in spite of distance from ports, Sheffield has long maintained a high position as a producer of fine quality steel and of cutlery made from it. This position was gained ere coal came into use, and the two main factors at first were water-power from the steeply-falling Don, and charcoal from the wooded slopes. The utilisation of these assets in days when workmen had not as yet been forced to become machine-tenders added another asset, that of traditional skill, an asset of prime importance which the nineteenth century squandered recklessly. Prof. Desch says that the cementation process for making steel is now known to have been a Tyneside invention of the early seventeenth century, but it developed at Sheffield, an example of cultural importation helping forward local relations between men and their environment, and he pleads for deeper study of these relations through the regional survey of Sheffield, which is getting to work. We are happy to note that Prof. Desch is the chairman of the committee concerned, and that the Geographical Department of the University of Sheffield is actively concerned in this valuable effort.

Some aspects of the regime of the Nile are discussed by Dr. H. E. Hurst in the Geographical Journal for November. The problems relating to Lake Tana and the Blue Nile are of special interest at the present moment. The period of greatest importance in the irrigation of Egypt is from March to July, when the Nile is lowest and has to be supplemented by water taken from the niver in December and January and stored in the Aswan reservoir. In April and May. when the Nile is at its lowest, the White Nile contributes 85 per cent. of the total discharge and the Blue Nile only 15 per cent. The portion of the Blue Nile supply which comes out of Lake Tana is only onethirteenth of the total discharge of the Blue Nile. In other words, the greater part of this supply enters the river between Lake Tana and the Sudan. This part of its basin is little known. It is a deep rugged valley in which travel is difficult. At least two large streams enter the Blue Nile within a hundred miles of the Sudan boundary but their discharge has not been measured. Lastly, it may be noted that the White Nile is much more important than the Blue Nile to Egypt, and that it has now been shown that the Sobat and the Lake Plateau contribute about equal parts to the supply of water in the White Nile The lake plateau supplies come mainly from Lakes Albert and Victoria, and the rest from the Semliki and Lake Edward.

The essential features of several types of metallurgical photomicrographic apparatus were described in an article in Nature of Oct 8. We have since had an opportunity of examining the large metallographic microscope made by Leitz of Wetzlar. The component parts of this apparatus are mounted on saddles which are capable of being moved along an optical bench consisting of a triangular bar similar to that used in two of the instruments referred to in the article. The stage of the microscope

consists of a right-angled casting screwed to the slide which is operated by rack and pinion at one side of the upright carrier. Two novel devices are incorporated in the camera of the Leitz instrument. The camera front has a small observation mirror at one side through which the entire area of the focussing screen can be seen. This is useful when the preliminary focussing and adjustment of the illumination are being made By means of it also the image may be watched during the actual exposure. The other device consists of a telescopic magnifier which is fitted into one side of a box attachment at the end of the camera and is in such a position that the fine adjustment screw of the microscope is within reach of the hand when the operator is looking into the magnifier. With the aid of the magnifier the image may be finally focussed. even after the plate carrier has been inserted, by examining it on a projection screen which can be brought into position immediately in front of the plate carrier. These devices enable the operator completely to control the focussing without having to move from the side of the apparatus.

In a paper on "Technical and Non-technical Management," read recently before the British Section of the Société des Ingénieurs Civils de France, Mr. Lucien A. Legros emphasised the dangers which may occur when industrial concerns are managed by persons without adequate technical knowledge. Management is usually divided into technical and non-technical departments, the former responsible for the processes of production and control of the employees and the latter concerned with the commercial side of the business. In most firms, Mr. Legros points out, there is a growing breach between the two functions of management, and there is a marked tendency for the technical side to become subordinate. But unless responsibilities are correctly allotted, and unless difficulties are mutually appreciated, management is not likely to be efficient. As it is, technical men have no commercial training, while non-technical managements have little knowledge of the conditions of the employees and of the relative values of skill, brawn, and brains, and do not appreciate the importance of research, standardisation, and technical education. Mr Legros admits that there are many difficulties in the way of coordination. In a few cases, the representation of technical employees on the Board of Directors might prove useful, though 'works committees' would, he considers, in general be a better solution provided they are independent of both employers' federations and trade unions. Indirectly, 'welfare work' may also be of importance. Mr. Legros concludes that if production is to be increased, technical education must be reformed and apprenticeship improved, while the real wants of the large but silent majority of the workers-stability of employment, immunity from 'rate cutting,' increased facilities for approach to the management, promotion through ability, and good foremanship-will have to be considered by non-technical managers.

An article by E. G. Fischinger in the Elektrotechnische Zeitschrift for June 2 gives an interesting history of one of the earliest high-tension lines in Europe. The power is generated at Luachhammer in Prussia and is transmitted at a pressure of 100,000 volts to the rolling mills at Riesa. It began working in January 1912. The chief difficulties encountered were with transformer breakdowns. After being in operation for some time, the mutual forces between the coils loosened them and the constant rubbing chafed away the insulation and caused short circuits. The strings of insulators supporting the high tension wires also caused trouble. This was traced to unequal expansion caused by heating and cooling, which developed cracks in the surface of the porcelain. This difficulty was overcome by using insulators of a new design. Like similar lines elsewhere, interruption of the supply was sometimes caused by large birds alighting on the wires and being electrocuted. In the south of France and in Switzerland, many eagles, large owls, and other birds of prev and capercailzie have been electrocuted by overhead high tension wires. Short circuits can be caused in this way. The author states that in the early days no less than thirty buzzards were electrocuted in rapid succession. He naively adds that after this the birds learned to keep away from the wires and there were no more short circuits. In our opinion, this diminution in the number of large birds, some of which are useful vermin killers, is much to be regretted. More thorough precautions should be taken to prevent such accidents. Other difficulties arise from the mechanical oscillations sometimes set up in the lines and from the ice formed on them in cold weather. The latter is easily got rid of, however, by slightly raising the temperature of the wires by sending an electric current through them.

In the Quarterly Review for October, S. L. Bensusan gives a survey, based on personal investigation, of current agricultural conditions in England. While he admits that in many cases the farmer is suffering through no fault of his own, he considers that where natural conditions are at all favourable, the best men are either holding their own or making small profits. Failure to realise the transitional nature of the industry accounts for the losses of most of the unsuccessful farmers, the situation being aggravated by the pessimistic attitude adopted by the press and others. He points out that the real solution lies in the development of new fields of activity, newer varieties of wheat, for example, being a safer remedy than the raising of a tax on imported flour. Sugar beet, he considers, offers the most hopeful prospects at the present time and serves a double purpose in that it relieves unemployment by creating labour both in field and factory. However, the financial assistance from the Government is largely responsible for the present success of the industry, so that the farmer must be able to increase his yield per acre and also to ensure that he receives a fair price from the factory before he can hope to compete with foreign countries. Amongst other changes quoted are those concerned

with stock, the methods now in use being uneconomic and not supplying the real needs of the market. Baby beet, small readily matured mutton and standardised pigs are the lines upon which the farmer must develop if he is to keep abreast with modern demands. Milk production should be one of the most profitable industries, particularly since the new methods of intensive grass farming have proved so successful.

It is announced that Mr. John D. Rockefeller, Jr., has offered to the Government of Palestine a sum of 2,000,000 dollars for the building and maintenance of a museum in Jerusalem if the Government will provide the site. The offer has been accepted by Lord Plumer on behalf of the Palestine Government. One of the conditions of the gift is that the museum should be purely archæological. Stops are now being taken to expropriate a site known as Karm esh Sheikh, which is outside the walls near the north-east corner of the walled city and opposite Herod's Gate. This munificent gift will provide a much needed relief from the present madequate accommodation.

Mr. Thomas Alva Edison has been elected an honorary member of the Institution of Electrical Engineers.

THE Council of the Yorkshire Philosophical Society has elected Mr. C. Tate Regan, Director of the British Museum (Natural History), and Dr F. A. Bather, Keeper of the Department of Geology, British Museum (Natural History), as honorary members of the Society.

SIR CHARLES CLOSE, formerly Director-General of the Ordnance Survey, has been appointed by the Council of the Royal Geographical Society, president of the Society until the anniversary meeting in June next in succession to Dr. D. G. Hogarth, who died on Nov. 6.

The Wellington (N.Z.) correspondent of the Morning Post announces that Dr. R. J. Tillyard, chief of the biological department, Cawthron Institute, Nelson, New Zealand, has been appointed chief entomologist to the Commonwealth of Australia. He will still remain in charge of the Empire Marketing Board's research work against the blackberry pest in New Zealand.

The Secretary for Mines has appointed the following to be a Committee to report to the Safety in Mines Research Board from time to time on, and to superintend research required for, the improvement of mine rescue apparatus and equipment: Mr. Robert Clive (chairman), Mr. James R. L. Allott, Mr. (f. L. Brown, Dr. J. S. Haldane, Mr. W. E. T. Hartley, Mr. P. S. Hay, Prof. J. A. S. Ritson, Mr. J. H. Thorne, Dr. R. V. Wheeler, and a representative of the Chemical Warfare Research Department. The Secretary of the Committee is Mr. E. A. Shearing, of the Mines Department, to whom all communications on the subject should be addressed.

THE library of the late Sir Arthur E. Shipley is to be sold by auction at the Corn Exchange, Cambridge, on Tuesday next, by Messrs. Catling and Son, 6 St.

Andrew's Street, Cambridge. Among the items to be offered are long runs of scientific series and serials. Catalogues are obtainable from the auctioneers.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:-An assistant master at the Wycombe Technical Institute mainly for mathematics and physics or engineering science—The Principal, The Technical Institute, Wycombe, Bucks (Nov. 28). A public analyst for the Borough of Lewisham-The Town Clerk, Lewisham Town Hall, Catford, SE.6 (Nov. 29). Inspectors under the Agricultural Wages (Regulation) Act, 1924 -The Secretary, Ministry of Agriculture and Fisheries, 10 Whitehall Place, S.W.1 (Nov 30). A student probationer at the Millport Marine Station, Cumbrae, Buteshire—The Secretary, Scottish Marine Biological Association, 88 Bath Street, Glasgow (Dec. 3). A chief engineer to the Manchester Steam Users' Association —The Executive Committee, Manchester Steam Users' Association, 9 Mount Street, Albert Square, Manchester (Dec 6). A woman blochemical research assistant at the Low Temperature Research Station, Cambridge; also two laboratory assistants, one for routine storage experiments, physical measurements, etc., and one for chemical analyses of animal tissues, preferably with working knowledge of bacteriology The Superintendent, Low Temperature Research Station, Downing Street, Cambridge (Dec 10). A headmaster of the Heaton Secondary School for Boys, Newcastle-upon-Tyne - The Director of Education, Education Office, Northumberland Road, Newcastleupon-Tyne (Dec. 17). A plant physiologist and a plant pathologist for banana research at the Imperial College of Tropical Agriculture, Trundad, B.W.I.—The Secretary, Imperial College of Tropical Agriculture, 14 Trinity Square, E.C.3 (Dec. 30). A woman assistant lecturer in the Department of Hygiene and Public Health of the Battersea Polytechnic—The Principal, Battersea Polytechnic, S.W.11. A junior research metallurgist at the Mond Nickel Company, Ltd. - The Secretary, Research and Development Department, The Mond Nickel Company, Ltd., Victoria Station House, S.W.1.

# Our Astronomical Column.

DISCOVERY OF A NOVA.—A new star of the tenth magnitude was discovered at Bergedorf Observatory by Prof. Schwassmann and Dr Wachmann on Nov. 18 at 11 P.M. in R.A. 5h 15m 12s, N. Decl 16° 38′. The position is in Taurus, close to the boundary of Orion, 9° east of Aldebaran, and about 12° from the middle of the Milky Way.

New Comet.—A new comet, the ninth of the year, and therefore designated 1927 j (the letter i is usually omitted in this connexion, to avoid confusion), was discovered by Dr. Schwassmann and Herr Wachmann at Bergedorf Observatory on Nov. 15 at 21<sup>h</sup> 33 3<sup>m</sup> U.T., in R.A. 1<sup>h</sup> 32<sup>m</sup> 12<sup>s</sup>, N. Decl. 20° 53′, Daily motion—24 sec., south 2′, magnitude 14; the announcement was made by the I.A.U. Bureau at Copenhagen.

Assuming uniform motion, the new comet's position on Nov 26 is R.A. Ih 28m, N. Decl. 20° 30′, about 5° west of Beta Arietis; it crosses the meridian about 8.48 P.M., at an altitude of 59°, and is thus very well placed for observation. Its slow motion suggests (but does not prove) that it may be at a considerable distance from sun and earth, in which case there is a fair prospect of its brightness increasing. It is sufficiently near the ecliptic to lie within the zone covered by minor planet photographs, and presumably it was incidentally discovered in the course of minor planet work; but as the telegram contains no expression of doubt, it may be assumed that the image is of a decidedly cometary character.

The Return of Encke's Comet.—This, the best known of all the short-period comets, was detected by Prof. G. van Biesbroeck at Yerkes Observatory on Nov. 13d 1h 19m 5 U.T., m R A. 22h 57m 8s·2, North Decl. 8° 54′ 13″; mag. 16. Perihelion will be passed in 1928 on Feb. 19·71 U.T., the other elements being, according to L. Matkiewicz (Astr. Nach., No 5521),  $\omega$  184° 55′ 43″ 20, i 12° 31′ 53″·43,  $\Omega$  334° 33′ 56″·43,  $\phi$  58° 9′ 27″·57, period 3·286435 years, equinox 1927·0. The comet is at present too famt for ordinary observors, but it should be visible with small instruments in the evening sky in January. After that it goes south, and must be left to southern observers.

This is the thirty-seventh observed apparition of the comet, a much larger number than that of any other comet; Halley comes second with twenty-eight. Encke has not been missed at a single return since 1819,

It is the eighth comet detected this year, and so bears the designation 1927 h; four of the eight were expected periodic comets, the other four were unexpected ones, though one of them (Gale) has proved to be a short-period comet.

SUNSPOT RECORDS FROM ARIZONA AND CALIFORNIAN TREES.—Some years ago, Mr. A. E. Douglas noted that a correlation could be traced between the sunspot curves and the size of the annual rings in the great trees of California. Since the tree records are available for thousands of years in the past, it is possible, once the relationship is established, to carry back the sunspot record into periods for which no data were formerly available. It will be remembered that Mr. E. W. Maunder noted a long period at the end of the seventeenth and beginning of the eighteenth centuries in which sunspots were exceedingly scarce, and the eleven-year cycle seemed to be in abeyance. Some people even suggested that the cycle might not have existed until the eighteenth century. The tree record gives new information on this point.

An article by Mr. Douglas in Jour. Roy. Astron. Soc. of Canada for September discusses the records of a number of Arizona pimes. He states that he had noticed the flatness of the curve of sunspots as given by the trees at the period noted by Mr. Maunder before he saw the conclusions of the latter. Carrying the research further back, he has found other periods at which spot activity seems to have been temporarily suspended. Between 1000 B.c. and 300 B.c. activity was slight, then a more active period began. There were other lulls between A.D. 400 and A.D. 650, and between A.D. 900 and A.D. 1200. In the same number, Mr. R. E. De Lury discusses some fossil trees, the estimated age of which is 300,000 years, and shows that the eleven-year period was then in evidence.

This study also affords evidence of the close correlation between sunspots and weather that exists in some districts of North America; in Great Britain the correlation is much less evident, if it exists at all.

THE DOUBLE AXE IN ETRURIA. -In Man for November, Mr. J. A. Spranger has noted examples of the occurrence of the double axe in Etruria in vase paintings, emerary urn reliefs, on bronze mirrors, as votive offerings, on coins, in tombs, and on a grave stele, with the view of their throwing light upon the Ægean or Asiatic origin of the Etruscans. It has, however, to be borne in mind that the occurrence of the cult does not necessarily mean that they brought it with them ab initio; it may have been introduced later in the course of their wide commercial relations. The evidence is by no means extensive, and, further, any conclusion must be tentative and hable to be upset by further discoveries. It would appear that the double axe was known from early Etruscan times, as is shown by the unique grave stele in the Florence Museum,—the oldest inscribed Etruscan monument known, and the only one bearing an unmistakable double axe. Further, the later Etruscans were aware of its value as a symbol of Dionysus, and a weapon connected with sacrificial rites. It is, however, at Vetulonia that the best evidence is found of its symbolic value, where it occurs as an emblem of power with the iron fasces in "the Tomb of the Lictor." Yet nowhere does it occur as a cult in the Cretan sense. It is rather evidence of 'Mycenæan' culture affecting the ancestors of the Etruscans.

Obsidian.—In Ancient Egypt for September, Mr. G. A. Wainwright discusses the possible sources of the objects made of obsidian which have been found in ancient Egypt. As obsidian or volcanic glass is found only in certain areas, its presence in a nonvolcanic country is a proof of trade communication. Unfortunately, it is not at present possible to identify positively by petrological tests the place of origin of any given piece of obsidian. Hitherto it has been generally thought, and almost universally the tendency among anthropologists to conclude, that obsidian in early times came from Melos; but it has also been recognised by some that other sources are possible. The abundant use of obsidian in Armenia and Mesopotamia militates against a Melian origin. Not only has obsidian been reported to occur in quantities in Armenia, but also the distribution of finds of obsidian implements in Armenia and Eastern Asia Minor and its relation to the distribution of flint implements, points to Armenia as a centre of use, with a peripheral contact with flint, where obsidian and flint are used side by side, until the flint entirely takes the place of obsidian. With this the distribution of obsidian in western Asia also well may be taken to agree. The farther from Armenia the rarer obsidian becomes, until in Anau, Turkestan, Palestine, and Egypt it becomes a rarity. other hand, its frequency in Mesopotamia, which is thus an exception in the peripheral distribution, may be accounted for by the facility of communication with Armenia by the river system. Several considerations equally point to an early connexion between the north and Egypt through Syria, such as, for example, the origin of barley, wheat, and the vine in Syria, or in the case of the last named, perhaps Armenia; as well as the intrusion of 'Armenoids' into Egypt in predynastic times. Armenia, therefore, rather than Melos, is the probable source of the Egyptian obsidian, communication being also easier in this case than with the Abyssinian obsidian fields.

Norwegian Decapods —Mr. James A. Grieg ("Decapoda Crustacea from the West Coast of Norway

and the North Atlantic." Bergens Museums Aarbok, 1926 Naturvidenskabelig rackke No. 7), records some rare decapeds obtained recently from the west coast of Norway and also gives a list of decapods collected by the Michael Sars between 1900 and 1914 during her expedition along the Norwegian coast and in the North Atlantic. There is not much system in the list, for we have Porcellana, Eupagurus, and members of the Thalassinidea sandwiched in, for apparently no reason at all, between species belonging to the Brachyura. It is interesting to compare these records with the British fauna. Eurynome aspera appears to be very rare, also Stenorhynchus longirostris, Inachus dorsettensis and I. dorynchus. Many other common British species apparently occur only occasionally in Norway. All breeding specimens are recorded, making these notes really valuable for reference. Amongst the four species of Pasiphæa, P. multidentata Esm. is well represented in the fjords, and it is shown that it is in berry from January to September, the breeding season thus spreading over a long period, for mature eggs occurred both in March and September, possibly showing two breeding seasons. Among the rare deep-water forms in the young fish trawl collected by the Armauer Hansen was one specimen of that peculiar crustacean Eryoneicus faxoni Bouv., 32 mm. long, which has been shown by Sund to be almost certainly the young of Polycheles sculptus Smith.

TRANSLOCATION IN THE COTTON PLANT.—Problems of vital interest to cotton growers are investigations of the factors regulating the shedding of buds and young bolls, the variations in form and development of the cotton plant from climatic and other causes, and the condensation of sugar to form cellulose in the lint hair. T. G. Mason and E. J. Maskell, of the Trinidad Cotton Research Station, have tried to elucidate these special problems by investigating the wider general problem of the translocation of nutritive substances in the cotton plant, and their local distribution to leaves, roots, flowers, seeds, and limb (Empire Cotton Growing Review, vol 4, No. 4). Their results confirm in part some obtained for other species by Prof. O. F. Curtis, of Cornell University. A strain of Sea Island cotton was used in the experiments, and the work consisted essentially in the analyses of samples of leaves, stems, and bolls collected at specified times from plants treated in certain definite The bark and wood were analysed separately. It was found that in the leaf both sugar and reserve carbohydrate fluctuated markedly, the quantity rising during the day and falling during the night. In the bark there were well-marked changes in total sugar concentrations, which followed closely on those of the leaf, with a lag of about two hours. No appreciable diurnal fluctuations could be demonstrated in the case of the wood, either in total sugar concentration or in reserve carbohydrate. Diurnal changes of sugar concentration in the holl were similar to those in the bark. The effects of ringing shoots were very marked. Above the ring sugar concentra-tion rose rapidly; below the ring the concentration fell as rapidly. In further investigations on the particular channel of transport, it was found that sugar continued to pass down a stem through a region in which bark and wood were separated by a ring of paraffined paper, and would also pass down into a seven-inch flap of bark continuous with the bark of the stem at its upper end, but separated from the wood throughout the whole of its length. The authors conclude that the bark forms the main channel of longitudinal transport.

Soil Sterilisation.—The Ministry of Agriculture has issued an illustrated leaflet (No. 209) describing practical methods of soil sterilisation for glasshouse crops. Although such treatment of the soil was formerly considered an expensive luxury, the modern grower has come to regard it as a necessary form of insurance, the question now being which method is the best to adopt. The two principal agents suitable for soil sterilisation are heat (steaming or baking) and chemical compounds such as cresylic acid Special attention is paid in the leaflet to the former, as it is shown to be both more effective and economic. Small quantities of soil may conveniently be sterilised by baking, the best results being obtained if the soil is in good condition and reasonably moist when treated, and is then stored for six weeks before being planted. Overbaking renders the soil infertile. Steaming, however, is the more usual method of treating the soil, and many ways of applying it are described with several illustrations. The choice of the steaming method must depend on the degree of soil sickness, as some allow of a deeper penetration than others. Eel-worm trouble, for example, cannot be eradicated by a superficial steaming. A repetition of the treatment is recommended every four years if a satisfactory standard is to be maintained, and sterilising should be completed by the middle of January, as it is advisable to flood the soil after steaming, and sufficient time must be allowed for it to dry before the crop is planted. Preparation of the soil before treatment is essential for success; dry, open soils steaming better than wet ones. Nitrogenous manures should not be applied to recently steamed soil unless it is in very poor condition, as the treatment induces an accumulation of nitrogen. A dressing of potash, and occasionally of phosphate, however, may be given with advantage. With regard to chemical treatment, cresylic acid is the most usual agent employed, but it is much less effective than steam, owing probably to the difficulty of obtaining such intimate contact with the soil particles. Further, it is necessary to apply the acid annually, so that the higher cost of steaming is approximately counterbalanced by the less frequent applications required. Emphasis is laid on the necessity for care in all soil-sterilising operations, as the work is rendered useless if the proper precautions are neglected.

'EDELMIST,' A NOVEL FORM OF FARMYARD MANURE. -An illustrated account of a new method of making farmyard manure, which has aroused considerable interest amongst farmers in Central Europe, is given by A. Cunningham in the Scottish Journal of Agriculture (vol. 10, p. 434). The manure produced by this process is known as 'Edelmist,' and is claimed to be superior to dung produced in the usual way even under the best conditions The chief feature in its preparation is that active fermentation is encouraged during the early stages, the dung being piled up loosely in shallow layers to secure the most favourable conditions for aeration. When the temperature has risen to 55°-65° C, the heap is thoroughly compacted by tramping, covered with a loose layer of fresh dung and allowed to remain untouched for 3 or 4 months. Several advantages are claimed as a result of the fermentation process, the most important being the - fact that the easily decomposable organic constituents of the straw are broken down, so that any retardation in the rate at which the nitrogen becomes available to the plant is avoided. Further, the high temperature is probably fatal to weed seeds and plant or animal pests. The tramping which follows the fermentation stage results in the exclusion of air, and in consequence the manure contains relatively few organisms, and can therefore be stored for some

length of time without suffering from undesirable changes. The losses incurred during the making of Edelmist are quoted as about one-half those of farmyard manure. The results of field experiments are somewhat variable, but the superiority of Edelmist over ordinary dung seems clearly indicated. The process is protected by British patent, the patentees providing plans for dungsteads, the cost of which they estimate would be repaid in from 3 to 5 years. Although the present results are quoted from Germany, where the farming conditions are somewhat different from those in England, yet the Edelmist process must be regarded as a distinct advance on the ordinary, and often very unsatisfactory, methods employed in the storage of dung in Great Britain.

RAINFALL IN BELGIUM.—It is satisfactory to note that the military occupation of Belgium from 1914 until 1918 did not result in the complete disorganisation of an important undertaking in the way of chmatological research that had been begun in that country in 1909. In that year, a simple uniform system of rainfall measurement was organised with the object of obtaining a long series of daily observations which would enable the normal rainfall for each month of the year over the whole country to be obtained. Thanks largely to the efforts of J. Vincent, the number of observers supplied with standard instruments had reached 311 by the end of 1913. This number may seem small compared with the five thousand which represents roughly the number of contributors to the British Rainfall Organisation. It was reduced, moreover, to a bare hundred by the end of 1918. Nevertheless, this network has been found to be sufficiently close to determine the general characteristics of the rainfall of the country as a whole. The records for the seventeen years 1910 to 1926 have been utilised for this purpose by E. Vanderlinden, and the results of his researches appear in Vol. 2 of the Mémoires de l'Institut Royal Météorologique de Belgique under the title "Sur la distribu-tion de la pluie en Belgique." In addition to ordinary monthly means for these seventeen years, corrected means are given which allow for the fact that these years were mostly characterised by rainfall m excess of the average for the forty years 1887-1926, judging from the records made at Uccle. The monthly means show that most rain falls in the southeast, where the highest ground is situated. It seems clear that the moist winds from the Atlantic yield up more of their moisture here than on the low ground discussion of the abnormally dry weather from Aug. 1920 to Oct. 1921, a drought apparently without precedent in Belgium in historic times. In this connexion accounts are given of all notable droughts of which records have been found since the year 1245. Some figures with regard to the maximum intensity of ramfall are worthy of note. They include a fall of 25 mm. in six minutes at Turnhout on July 10, 1889, and 200 mm. in three and a quarter hours at Louvain on May 14, 1906.

Testing Iron by means of Ring Specimens.—In practical work it is usual to make the ratio of the radial thickness of a ring specimen to its diameter to be about a tenth. In this case the average magnetic force on the inner circumference of the ring is about ten per cent. greater than at the outer circumference. In general, therefore, an error is introduced into the results owing to the distribution of the magnetic flux not being uniform. M. G. Lloyd, of the U.S. Bureau of Standards, has computed the errors involved for various ratios of radial thickness

to mean diameter on the assumption that the permeability is constant. In the Journal of the Institution of Electrical Engineers, p. 932, 1927. E. Hughes has made computations taking into account the variation in the permeability of the iron over the cross-section. Computing in this way, he finds that the errors given by Lloyd are almost invariably too small or too large. He discusses the relationship between the actual hysteresis loss in the ring and that found by using alternators and by using a ballistic galvanometer. Reference is made to the desirability of using a larger ratio of radial thickness of diameter than is customary, in order that any error due to mechanical strain produced by punching, etc., may be reduced.

STRENGTH OF ELECTRIC LAMPS.—The important paper on the mechanical strength of metal filament electric lamps which was read to Section G of the British Association at Leeds on Sept. 5 by Mr. Murgatroyd is published in Engineering for Nov. 4. The earliest filament lamps used platinum, which has a melting point of only 2028° Kelvin, whereas tungsten, which is now used, has a melting point of 3655° K. From theoretical considerations, Mr. Murgatroyd deduces that a temperature of about 2020 To which the transfer of about 2020 To which the transfer of about 2020 To which the transfer of about 2020 To which the transfer of about 2020 To which the transfer of about 2020 To which the transfer of about 2020 To which the transfer of t 6270° K. would be the most efficient for illumination. He also deduces that the larger the crystals of the metal used in a filament the stronger the filament should be. He says that the size, shape, and orientation of the crystal determines its mechanical strength. Using a simple apparatus he carried out 'shock' tests on electric lamps. He obtained the following An electric filament lamp is weaker mechanically when it is incandescent than when it is cold. Contrary to ordinary ideas, the gas in a gas-filled lamp does not add to its strength. Spiral filaments also are not necessarily stronger than straight filaments. He emphasises that the chief factor in determining the mechanical strength of a metal filament lamp is the structure of the filament material. Since high temperature tends to weaken a lamp, it might be thought desirable to increase its strength by working it at a lower temperature and therefore at a lower luminous efficiency. This, however, would be a retrograde step. The 60-watt gas-filled lamps which he tested when working normally were relatively strong in spite of the high temperature. This fact should encourage the user to insist on higher strength in all lamps without having to resort to uneconomical operation. For low candle power lamps, a squart squirrel-cage type of mounting has many advantages in the present stage of develop-

The Slotted Wing in Aeroplanes.—In aviation a difficulty arises in connexion with the use of slotted wings from the fact that with the slot open the maximum lift usually occurs at an angle of incidence considerably higher than with the ordinary unslotted wing. In order to benefit to the fullest extent from the high lift co-efficient arising from the use of the slot, it has been necessary for the machine to have a high under-carriage, with some discomfort to the occupants both on taking off and on landing. An adjustable rear flap to some extent overcomes this difficulty (Aeronautical Research Committee: Reports and Memoranda, No. 1063 (Ac. 245); Model Experiments on R.A.F. 31 Aerofoil with Handley Page Slot. By H. B. Irving, A. S. Batson, and D. H. Williams.—London: H.M. Stationery Office. 6d. net). When down, such a flap, in effect, increases the angle of incidence of the wings and simultaneously possesses the additional advantage of giving an in-

crease in maximum lift over that provided by the slot.

FLUID VORTICES.- With the object of supplying data for a more complete mathematical treatment of the vortices formed in a fluid about a body rotating m it, or if this should prove impossible, for a qualitative treatment of the problem, Messrs. T. Terada and K. Hattor, of the Aeronautical Research Institute of the University of Tokyo, have made a photographic study of the forms of these vortices under various boundary conditions. Spheres, cylinders, and discs have been rotated in cylindrical and rectangular vessels sometimes alone, sometimes in pairs, with the directions of rotation the same or opposite, and the torque on the outer vessel has been measured. The vortices produced in the liquid show great persistence and accommodate themselves to widely differing boundary conditions, behaving as if they were rings of deformable material possessing a form of elasticity. No hydrodynamic theory has been found capable of covering the whole of the effects observed. The paper appears in the August Issue of the Report of the Aeronautical Research Institute, Tokyo, and is well illustrated by photographs.

VERTICAL ILLUMINATION OF METALLURGICAL SPECI-MENS.—In the Journal of the Royal Microscopical Society for June 1927, Mr. Conrad Beck discusses from an optical point of view the best method of illumination of metallurgical specimens with the vertical illuminator, and, in particular, the method used by Mr. Harold Wrighton, whose photomicrographs showed a resolution of lines about 1/150,000 meh Since the resolution depends on the aperture of the object-glass, the whole aperture must be utilised to make the best use of the magnifying power. This condition cannot be realised when a prism or an opaque reflector is used. To obtain the best results, a transparent reflector is necessary of a size at least as large as the back lens of the object-glass. Other two conditions are shown to be essential for perfect illumination: the light must (1) be centred and (2) be in focus upon the object. To fulfil the three conditions an optical bench arrangement is necessary. One lens is used to produce a suitably sized image of the source, and an iris diaphragm to vary the size of this secondary source. A second lons focusses the diaphragm at a position close to the back lens of the object-glass, whilst a second diaphragm allows the area of the field to be controlled exactly. The arrangement also permits the use of the method proposed by Prof. Carl Benedicks of obtaining various types of oblique illumination by the use of patch stops. The desired effect can be obtained by placing a suitable stop close to the first diaphragm.

THERMAL DISSOCIATION OF CARBONYL Chloride.—Phosgene, or carbonyl chloride, decomposes on heating into carbon monoxide and chlorine, and measurements of the dissociation constant by chemical and physical methods are described by H. Ingleson in the Journal of the Chemical Society for September. The gas was heated in a quartz bulb and the chlorine determined iodometrically or by the rise in pressure measured on a manometer. The results from the two methods agree satisfactorily and the usual straight line relationship holds between the reciprocals of the temperatures and the logarithms of the dissociation constants. The approximate heat of the reaction was found to be 25,500 cal. at 416°, in agreement with the value obtained by Thomsen. The decomposition of carbonyl chloride appears to be catalysed by the chlorine which is formed, and this was first noticed by Christiansen.

the many years it has been customary to test the lineary of telephone receivers and micro-comparisons against instruments selected. The international committee on long-committee on long-commit

in a paper real by Mr. B. S. Cohen to the Instituon of the rical Engineers on Nov 17, a record is and the methods hitherto employed for telephone operators of dime transmission standardisation. He are the subset the new methods and the modifications of the old methods now being introduced. The paper is migrity by ed on the results obtained in the research

Januaratoric, of the Post Office.

Here the adopts a nomenclature used by the Post Office which is becoming standardised. By the volume meant its loudness or amplitude, and by distinction in the reproduction of water and. A distinction is made between articulation and siligibility. Articulation means the compactive of fection in the reception of sounds not conveying bleas, whilst intelligibility means the compactive is rection in the reception of sounds conveying bleas. These depend on the volume and distinction of the sound as well as on external and contact the sound as well as on the sound as well as on the sound as well as on the sound as well as on the sound as well as on

easy to understand what telephone enfrequency is of all the confidence of standard cable. This has become and the transmission unit is now generally, er as the logarithmic ratio of two powers would give.

or of two currents, the former being a logathe base 10 and the latter being to the Napierrandses. It is proposed to call the former the 'bel' after the inventor of the telephone, and the latter the 'néper.' Feeling runs so high between the advocates of these two units that, faute de mieux, it has been decided to sanction the use of both.

The method of testing articulation is to send twenty-five different sounds to a recording observer slowly and uniformly. The percentage of the sounds received correctly measures the articulation. It is satisfactory to learn that with good, solid back microphones there is practically no ageing effect New microphones have to pass a comparative test against a standard. One of the tests of the new telephone receiver was to jar it by dropping it from a definite height on to a steel plate 100,000 times

This had little if any effect on its efficiency.

In the latter half of Mr. Cohen's paper he discusses the kind of apparatus most suitable as a telephone standard. He also discusses the frequency range for broadcasting, etc., recommended by the international committee. The 'ideal' range covers perfect reproduction of speech, music, and most noises. In this case all sounds having frequencies lying between 30 and 10,000 cycles per second must come through the apparatus. For 'high quality' speech and music, the necessary range includes all sounds having frequencies between 100 and 5000; whilst for 'good quality' articulate speech, only sounds having frequencies between 200 and 3000 are required. From the point of view of articulation, the mean speech frequency is 1500 cycles. This means that the removal of all the components of the sound which have frequencies above 1500 gives the same quality of articulation as the removal of all the frequencies below 1500 would give.

# The Mellon Institute.

TING developments of the work of the Institute in the University of Pittsburgh, i the last annual report, are the new s for analytical chemistry under Dr. and for 'pure chemistry' under Dr. L. H. When the Institute was originally estabquestion of the position of research in mistry and other subjects was considered. I contradict the director's statement that ire science investigator, who is the father fforts in industrial research, falls the glory those discoveries that lie at the groundour knowledge of nature, and of all our utilising natural products." But the uestion is whether 'pure' research should sed in another department of the Univerthe control of a director specially interested science, and, if so, what haison should een such department and the Institute, r an Institute primarily dedicated to research should make provision also for search. Apparently the original decision eversed, or perhaps it would be truer to ne development of the work of the Institute red necessary some provision for pure In a research institute of this magnitude, or advisory and consultative work both in chemistry and in pure chemistry can understood. ogress of the Institute is exhibited in the

report in the form of curves showing steady progress except for perturbations during the War period. The fellows, at present 102 in number, are at work in connexion with 58 industrial fellowships, and a sum of nearly £120,000 was paid during the last fiscal year in support of research in the Institute by the fellowship donors; and the total amount of money appropriated by companies and associations to the Institute during the first sixteen years of its work is approaching a million pounds, all of which was disbursed in sustaining fellowship research. These astonishing figures would have gratified the originator of the scheme, the late Prof. Duncan, and must give great satisfaction to the benefactor whose honoured name is associated with the Institute.

The Institute has published a bibliography of books, bulletins, journal contributions and patents issued from the Institute from the inauguration of the Industrial Fellowship system (March 1, 1911) to January 1, 1927. The director, Dr. E. R. Weidlein, expresses the hope that the list will serve a useful purpose, especially in libraries of other research laboratories. Incidentally, the publication gives convincing evidence of the success of the work initiated by Prof. Kennedy Duncan, of which particulars have been published from time to time in NATURE. The researches conducted in the Institute, with the financial support of industrial firms, cover a wide field in applied chemistry, physics, biology, metallurgy, and other subjects, and the long list of

able to restrict the entries to contribution interest to the exclusion of articles of a contribution of a contribution of a contribution of a contribution in the contribution of a contribution

# Insect Flagellates and Disease-A Study in Adaptation.1

LIC94

FLAGELLATES of the family Trypanosomide are for the most part parasites of the intestinal tract of invertebrates, chiefly insects. Infection is contaminative, one insect infecting itself from encysted stages of the flagellate voided in the faces of another. In African sleeping sickness the trypanosome lives both in the tse-tse fly and in man. It seems clear that originally these pathogenic flagellates were limited entirely to insect hosts, as the majority of the members

of the family still are.

It is found that certain lizards acquire an intestinal infection presumably by devouring infected insects. The flagellates finally adapt themselves to life in the lizard's intestine, whence in some cases they invade the blood stream. If the insect which causes the intestinal and blood infection when devoured by the lizard be one which sucks the blood, then such an insect might infect itself from the blood. The original contaminative method of infection of the insects from one another may still persist, though it may be no longer necessary. If it were lost a condition of affairs like that in Trypanosoma lewist would be reached. The flea ingests trypanosomes from the blood of the rat, and later voids trypanosomes in its fæces, which when eaten by the rat lead to infection. The infection is associated with development in the hind gut of the flea. In the case of sleeping sickness, trypanosomes taken up from the blood of man by the tse-tse fly develop in the anterior part of the alimentary tract and are inoculated into the skin when the fly feeds. Infection of man is inoculative and not con-

 $^1$  Substance of a paper read by Dr. C. M. Wenvon, C.M.G., C.B.E., F.R.S., to the Royal Society of Edinburgh on Qct. 21.

taminative as in the rat. The flagolla in the has moved from a posterior to an anter or station, else the tse-tse fly is not the original involvement for Surra of horses is transmitted by taballed flies i purely nechanical manner. The fly bites an fected animal, and if it feeds again within a faminutes on another animal, the trypanisomes who remain alive on or in its proboses are inventant. The chances of survival of the flagellar would agreater if it could establish itself in the flag a definite infection. It is possible that this has occurred in the state-tse fly; it would explain the development in the anterior part of the intestine. In his alternation oriental sore it has been shown that the parasite taken up by Phlebotomus develop in the anterior part of the intestine. Assuming that the said fly is the transmitter of these diseases, it has yet in he deferment how the flagellates are inoculated into human beings.

Flagellates have also adapted themsel es to life in plants. Studying such infections in Control America Strong has noted that plant bugs which hadron flagellates infect not only a Euphorbia but into a lizard which devours it. The inoculation of the flagellate from the lizard's intestine into the skin of a monkey caused an ulcer in which rounds that the flagellate persisted for more than two were the flagellate persisted for more than two were Though Strong's work undoubtedly required confirmation, it illustrates how insect flagellates originally confined entirely to the insect host, have adapted themselves to higher animals and plants and example in many cases led to the production of den

#### The Statistics of Accident Investigations.

AN important article has appeared in the Journal of the Royal Statistical Society (vol. 90, Part 3, 1927) on practical applications of the statistics of repeated events, particularly to industrial accidents, part of which had been read by Miss Newbold before the Society on April 26 last. Several times in these pages, articles dealing with accident investigations have been reviewed, and it is useful to have this very able summary of a number of separate lines of attack as well as the statistical details and tables. Research workers sometimes fail to understand some of the simpler laws of causation and reproduce their results in such a way as to render interpretation difficult or impossible. Averages are assumed without evidence to be what they seem to be, and comparisons are made between incomparable groups.

Miss Newbold's work shows the difficulties that confront the statistician when data have to be treated scientifically. She begins by a historical review of accident work and incidentally points out how complex are the problems involved. She considers the question first abstractly, looking upon an accident simply as an event, and assumes that we have a record of the numbers of such events happening to different people in certain periods of time and that the external conditions are uniform. Even with these assumptions, there arises the question as to whether the distribution of events among the individuals is a purely chance

one, and if it is not, to what extent are the underlying poculiarities masked by chance variations and how far we are able to strip off the mask and see the form of these peculiarities.

This involves a discussion of the mathematican treatment of such data and a consideration of after native methods. To know if a high accident of eater at a department is due to a few people of the entered conditions alike for all is of practical importance but is difficult to determine. On the whole, from a consideration of the work done so far, there come undication that the same people are likely to the curbon small and major accidents. Results, however are not sufficiently definite to provide a basis for infinite trative proposals, but the weight of the gradually accumulating evidence and the improvement in statistical technique show clearly that the work is

The discussion which followed the receiving of the, paper is also valuable, representing different pointer of view. Dr. M. Greenwood gave some distributions of the War the study of accidents be gradual development of the problem.

#### niversity and Educational Intelligence.

MBRIDGE.—The late Miss McArthur, formerly of in College, has left the residue of her estate, stated be not less than £4000, to the University for the ard of a prize or prizes for the encouragement of the dy of economic Listory

C. Rimington, Emmanuel College, has been re-Jected to the Benn W. Levy research studentship in

ochemistry.

The Financial Board has proposed to the University he purchase of the Balfour Laboratory from Newnham College, with the view of its being adapted to meet he needs of the Faculty of Geography.

Dr. R. Chodat has been appointed to represent the Juiversity at the celebration of the seventieth birthday of Prof. A. Pictet in Geneva, and Prof. Inglis for the coming centenary of the Institution of Civil

Ingineers.
The governing body of Emmanuel College offers to a research student, commencing residence at the University in October 1928, a studentship of the annual value of £150, tenable at Emmanuel College for two years, and renewable, in exceptional circumstances, for a third year. Preference will be given to a candidate who has already completed at least one but not more than two years of research studentship will be awarded in July, and applications should be sent so as to reach the Master of Emmanuel (The Master's Lodge, Emmanuel College, Cambridge, England) not later than June 30.

Edinburgh.—At the meeting of the University Court on Nov 14, it was announced that Lady Lyell of Kinnordy has presented to the Department of Geology valuable collections of minerals, rocks, and fossils, together with cabinets for keeping them. In addition, Lady Lyell has given many geological books, papers of historical interest, and a collection of autographed letters from scientific workers of note to the late Sir Charles Lyell.

London.—Messrs. J. Lyons and Co., Ltd., have contributed 250 guineas towards the establishment of

the proposed chair of dietetics.

Dr. J A. Braxton Hicks has been appointed as from Sept. I last to the University readership in pathology tenable at the Westminster Hospital Medical School. Dr. Hicks was educated at Epsom College (1896-1902) and Westminster Hospital Medical School. In 1907 he obtained the M.B., B.S. degrees with honours in athology, and in 1910 the M.D. degree in pathology of London and the D.P.H. (Cambridge). Since 1910 ne has worked in the Department of Pathology at the We +minster Hospital and Medical School, and since he aboratories were enlarged under the John Burford arlill Bequest, he has been director of the laboratories the Hospital and Medical School.

The King has approved the appointment of Prof. W. R. Halliday, professor of ancient history in the University of Liverpool, to be Principal of King's College, as from Jan. I next, in succession to Dr.

Ernest Barker, who has resigned.

OXFORD.—Profs. E. S. Goodrich and F. A. Lindenann have been appointed by the heads of the SCIEL

Library Auviso.
The Board of the ilty of Me... Mr. Arthur P. Dodds-Parker, of Magdalen

member of the committee for the control of the Lew-Evans Collection.

Prof. A. G. Tansley, Sherardian professor of botany, delivered his inaugural lecture on "The Future Development and Functions of the Oxford Department of Botany" on Nov 22.

The King has approved the appointment of Sir Edward Farquhar Buzzard to be Regius professor of medicine in the University, as from Jan 1 next, in succession to Sir Archibald Garrod, who has resigned.

ST. Andrews.—The University Court has appointed Mr D E Innes to be reader in geology in the University.

THE governors of Loughborough College invite applications for the award of five open scholarships in the Faculty of Engineering, each of the value of £75 per annum. The scholarships are open to British subjects from any part of the Empire, and are tenable at Loughborough College, Leics., England, for the period of the full diploma course. entrance examination for the session 1928-29 will be held on April 24, 25, and 26, 1928 All applicants must be not less than sixteen years of age on Oct. 1, Further particulars and application forms 1928 may be obtained from the College Registrar.

THE Council of the Royal Meteorological Society, with the view of encouraging the study of weather m schools, invites teachers to send in essays on that subject, for which three prizes will be given. The Council considers that the essay should include a description of the work which is actually being carried out or has been carried out by the teacher and his class The essays should be limited to 2000 words, but may be accompanied by examples of pupils' work. They should be received by the Society not later than June 30, 1928. It is hoped to publish the winning essay or essays in the Quarterly Journal of the Society. The essays should be forwarded to the Royal Meteorological Society, 49 Cromwell Road, London, S.W.7.

According to the statement for the year 1926-27 issued by the Rhodes Trust, there were 187 Rhodes Scholars in residence that year, of whom 93 were from the British Empire and 94 from the United States; 64 completed or gave up their scholarships. Of those in residence, 4 were taking mathematics, 32 natural science or medicine, and 2 forestry or agriculture. Sir Robert Borden, sometime Prime Minister of Canada, was the Rhodes Memorial Lecturer for the year and delivered three lectures on "Canada in the Commonwealth"; the lecturer for 1927-28 will be Dr. Abraham Flexner, of the Rockefeller General Education Board, New York. During the past year the Rev M R Ridley was appointed to the first Rhodes Travelling Fellowship; two further appointments, for which resident fellows, tutors, and lecturers at Oxford are eligible, will be made early in 1928. Information on the Rhodes Scholarships and Fellowships can be obtained from the offices of the Trust, Seymour House, Waterloo Place, London, S.W.1; in the United States, from President Aydelotte, Swarthmore College, Swarthmore, Pennsylvania; in Canada, from Mr. J. M Macdonnell, National Trust Company, Limited, Montreal, P.Q.; in Australia, from Dr. J. C. V. Behan, Trinity College, Parkville, Victoria; in South Africa, from Mr. P. T. Lewis, Court Chambers, Keerom Street, Cape Town.

No. 3030, Vol. 120]

, 1060.—The official record of the centy reads as follows "Memorandum that wovemb. 28, 1660, These persons following, according to the usuall custom of most of them, mett together at Gresham Colledge to heare Mr. Wren's lecture, viz. The Lord Brouncker, Mr. Boyle, Mr. Bruce, Sir Robert Moray, Sir Paul Neile, Dr. Wilkins, Dr. Goddard, Dr Petty, Mr. Ball, Mr. Rooke, Mr. Wren, Mr. Hill. And after the lecture was ended, they did according to the usual manner withdraw for mutual converse. .

November 28, 1867.—In a letter of this date, Gassiott told Tyndall the following story of Davy entering Pepys' shop in the Poultry. Showing him a letter Davy said, "Pepys, what am I to do, here is a letter from a young man named Faraday; he has been attending my lectures and wants me to give him employment at the Royal Institution—what am I to do?" "Do?" replied Popys, "put him to wash bottles; if he is good for anything he will do it directly, if he refuses he is good for nothing." no," replied Davy, "we must try him with something better than that." The sequel was that Faraday was employed to assist Davy in the laboratory.

November 30, 1845.—One of the most remarkable days in the history of railways was Nov. 30, 1845, the day fixed by the Board of Trade for lodging plans and specifications for new lines. Extraordinary measures were adopted for producing the documents and for getting them to London in time. No fewer than 1200 companies were started that year, the capital represented by the schemes amounting to £560,000,000. In 1846, 600 railway bills were actually brought forward, and it was then that 'the battle of the gauges' set in. It was, however, only on Brunel's gauges' set in. It was, however, only on Brunel' Great Western line that the 7-foot gauge was used.

December 2, 1846.—Some of the earliest experiments in arc lighting were made by Staite and Petrie, who worked together at various problems. To Petrie was due the invention of the first truly self-regulating are light, while on Nov. 28 and Dec. 2, 1846, he demonstrated the use of his light from the portico of

the National Gallery.

December 2, 1856.—On this day Friedrich and Wilhelm Siemens took out the British patent for their regenerative furnace, which a few years later found its most important application in the open hearth method of making mild steel by the Siemens Martin process—a process by which to-day more than 80 per

cent. of the steel of the world is produced.

December 2, 1857.—"The advantages of science in nautical affairs," said Mr. Fillmore, President of the United States, on Dec. 2, 1857, "have rarely been more strikingly illustrated than in the fact stated in the report of the Navy Department, that by means of the Wind and Current Charts projected and prepared by Lieutenant Maury, the Superintendent of the Naval Observatory, the passages from the Atlantic to the Pacific ports of our country have been shortened by about forty days." A writer three years later calculated that Maury's work saved the country more than 2,000,000 dollars per annum, and that a British sailing vessel on passage from England to Australia saved £1200 by the use of his charts.

December 3, 1847.—It was on Dec. 3, 1847, that Lyon Playfair wrote to James Young telling him of a petroleum spring in Reddings Colliery, Alfreton, Derbyshire, and suggesting he might turn it to account The flow of oil was only about 300 gallons a day and this rapidly diminished, but it was through this enterprise that Young was led to experiment on the distillation of oil from coal, and thus laid the foundation of the shale oil industry. R. S Edwards On g effect of ter, continuous viscosity of air: New measurements or or french man on the variation with temperature the vire of air over the range of 15°C, to 444 the first accuracy of the results obtained by the A. Winner The present measurements corrob onto thos previous observers and not those of Wuliams. concluded that there is no breakdown of Sutherland law in the region of 250° C., and that Satherland constant is constant over the whole of the range me tioned above.

P. Kapitza: Further development of the methor of obtaining strong magnetic fields. These fields are obtained for a short period of time only, as it in the possible to apply large powers to the coil was not overheating it. In this manner fields of 100,000 muss, have been obtained. It is now possible to use to the powers. In the place of accumulators, large points. ator by means of which powers up to \$40,000 kilowata can be obtained in the coil for the sec. (18, been week.)
Up to the present, magnetic forces to a faith
350,000 gauss have been obtained in volume of 2 c.c.

F. H. Rolt and H. Barrell: Contact of that surf were. The object of this investigation was to applied into the phenomenon of 'wringing' which is used extensionly m forming combinations of gauge blocks of the Johansson type. These gauges, which are of hard and steel, have their important surfaces finished to a light degree of flatness, and when brought mio intimute contact are found to adhere together very strongly. The adherence depends to a large extent upon the smoothness of the surfaces; so much so, that gauges having optically polished surfaces can be made to adhere when quite clean, whereas the having and lapped' finish require the introduct. fine film of oil or other liquid to prod a concelle Repeated wringing together of gauges to a shift but measurable wear of their surfaces the discourse is explained as the molecular attraction become the surface molecules of the gauges In the analysis surfaces, the average separation between the stateand the abuse cules on the two surfaces is considerably with smooth surfaces, and the function and the surfaces in the former case is to act as a link bety

widely separated molecules.

W. Mandell: The determination c moduli of the piezo-electric crystal Ro-electric properties, the magnitude of the offeet hering several hundred times greater than with effect is associated only with crysta. asymmetric structure, and occurs when submitted to mechanical stresses. Transformer oil .	$0.00032_{1}$	$-0.0006_{2}$
Medicinal paraffin	$0.00030_0^{-}$	$-0.0000^{-1}$
Paraffin oil · .	$0.00029_8$	$-0.0005^{2}$

#### THEORETICAL PHYSICS.

H. Levy and A. G. Forsdyke. The vibrations of an infinite system of vortex rings. In a previous paper the stability was examined of an infinite system of equal vortex rings situated in parallel planes with their centres evenly spaced along an infinite line and with their planes at right angles to that line. Instability was found to occur for disturbances confined to displacements of the centre of each ring along the central axis, the filament of each ring still remaining circular. The investigation is now extended to deformation of the vortex filaments. Conclusions are drawn regarding natural modes of vibration of the system; it is found, for example, that for any given ratio of radius of ring section to radius of ring there exists a critical ratio of ring spacing to radius, separating the region of stable oscillation from that of instability.

L. Rosenhead: Resistance to a barrier in the shape of an arc of a circle. The method is based upon the transformation introduced by Levi-Cività in 1906, and the approximation process used by Brodetsky. The value of the thrust and its line of action are obtained for barriers of both concave and convex camber, and for various angles of incidence. From these figures curves are plotted, from which the thrust for any particular camber and any possible angle of incidence can be obtained by interpolation. The results are interesting for the following reasons: (a) As the angle of incidence decreases, the centre of pressure, in the case of small concave cambers, moves

C. V. Raman and K. S. Krishnan: A theory of electric and magnetic birefringence in liquids. local polarisation field acting on any molecule must depend on its orientation. The Langevin-Born theory is accordingly modified so as to take this 'anisotropy of the polarisation field also into account and the modified expression for birefringence is in better accord with facts. As a rule the effect of the 'anisotropy' of the polarisation field is to diminish the magnitude of the birefringence to be expected, due to the fact that, in general, the longer linear dimension of a molecule tends to be also the direction of maximum electrical and optical susceptibility. The distribution of the molecules in a dense fluid therefore tends to be such that their mutual influence is equivalent to an apparent diminution in the anisotropy of the mole-

E. T. Whittaker: On electric phenomena in gravitational fields. It is a consequence of general relativity that when electromagnetic phenomena of any kind take place in a gravitational field, they are influenced by the field; that is to say, the Maxwell's equations of the electromagnetic phenomenon must be replaced by other equations which involve the gravitational curvature of space Two kinds of gravitational field are here considered, namely · (1) the field due to a single attracting mass and (2) a limiting case of this, which is called a quasi-uniform field: within these gravitational fields, electromagnetic phenomena are supposed to take place. The mathematical solutions of a number of problems correspond to well-known solutions in the classical Maxwellian theory. The results of the investigation are for the most part expressible only in terms of Bessel functions and of certain new functions which are introduced: but in some interesting cases the electromagnetic phenomena can be represented in terms of elementary functions, as for example the electric field due to an electron in a quasi-uniform gravitational field, and the spherical electromagnetic waves of short wave-length about a gravitating mass.

W. R. C. Coode-Adams: The refractive index of quartz. The characteristic frequencies in dispersion formulæ can now be obtained from the formula for optical rotation and applied to an equation of the Ketteler-Helmholtz type.

Physical Society, Oct. 28.—W. N. Bond The theory of liquid flow through cones. An approximate general solution is given of the hydro-dynamical equations for liquid flow through conical tubes of circular section, the errors due to the approximation being small for converging cones of small angle and for flow through similar diverging cones up to the speed at which the theory predicts turbulent motion.—H. P. Walmsley: The structure of the smoke particles from a cadmium arc. Using the powder method of X-ray analysis, the particles dispersed in air from a cadmium arc are found to be isometric crystals of cadmium oxide. From X-ray data, a density of 8.16 was obtained for the primary particles in the smokes—the normal density of cadmium oxide. Photometric measurements of the breadth of the lines showed that the primary crystals were of colloidal dimensions, values of  $5.8 \times 10^{-6}$  cm and  $4.9 \times 10^{-6}$  cm. being obtained in two cases. aggregation, the ultramicroscopic crystals grow along binary axes of symmetry, ie. they tend to unite on their 110 faces.

### Nationalism and Research.

MONG the many developments of recent disturbed conditions in China, there is one which has passed almost unnoticed, but nevertheless is of such moment to the world movement in science as to merit more than a cursory reference. This is the attitude which has been adopted by a section of educated Chinese towards the prosecution of certain branches of scientific research within the borders of China by non-Chinese workers. Objection has been taken to the exploitation, as it is regarded, of the relics of China's past by expeditions coming from Europe and America

In the spring of this year an article was circulated to the Chinese press by Kuo Wen, in which a joint statement was made on behalf of several Chinese scientific organisations in Peking, announcing the formation of a United Association to fight the efforts of various scientific expeditions to search for the remains of ancient man and other evidence of a palæontological and archæological character in various parts of China This manifesto had special reference to Dr. Sven Hedin's journey into the desert region of western China, but it was also undoubtedly aimed at the expedition of the American Museum of Natural History to Central Asia. It at any rate moved Mr. Roy Chapman Andrews, the leader of the American expedition, to a vigorous and lengthy reply in the North China Daily News in July last, in which he stressed the indebtedness of Chma itself as well as the world of science at large to this and similar expeditions for scientific research Since then it has been decreed that no specimens of birds may be exported from China, and only three scientific specimens of any other species of animal reference facilities in China, this decree will obviously greatly hamper identification and research. The later barring of Mongolia to the American expedition is ostensibly attributed to military and political reasons.

That the extent of China's indebtedness to western science is great is a matter which is beyond question. Nor would it be denied by many of the Chinese themselves. In the present instance the protest which is raised on an issue in relation to certain specific material, even though the motives underlying it are undoubtedly mixed, may be taken at its face value as representing a genuine opinion of a certain section, at least, of educated Chinese, and not solely as a reactionary reflex of a

conservatism which abhors all foreign intervention of any kind whatsoever It is rather the manifestation of an exaggerated, and perhaps it might be thought perverted, nationalism This attitude is by no means confined to China, it can be paralleled at the present day in other countries, and it has given rise to problems of considerable magnitude in the prosecution of scientific research in countries rich in remains of the past, in which a strong movement towards nationalism has led the more ardent spirits to desire the exclusion of foreigners from such studies, although the natives themselves are not always fully competent to undertake them. In Egypt this feeling was given emphatic expression at the time of the opening of the tomb of Tutankhamen, and it is the essence of the spirit in which concessions, much more strictly limited than in the past, are now granted to foreigners. In India the difference in conditions has for the moment obscured the result, though the problem affects a wider scientific field; but the substitution of Indians for Europeans in official posts of organisation and research cannot but affect such studies until parity of intellectual qualifications has been attained. In both cases a political theory is adversely affecting the vigorous and effective prosecution of research

Granting for the moment that nationalism were a possible or even desirable ideal in the prosecution of research, it must be abundantly clear that in countries which are only just beginning to advance along western lines of development, undue restriction of exploration and excavation defeats the very object in view. It closes the best avenue to scientific training open to the native student

In both Egypt and India, interest m historical and archæological matters is no recent growth, yet it is the application of methods of research developed in Europe by European scholars which has been so fruitful in results. China is an even more striking example of the advance in knowledge of the past which has been effected by foreigners. The interests of the Chinese themselves being turned in other directions, they had neither the inclination nor the technical training to look for and appreciate the importance of the evidence which lay under their feet until attention had been directed to it by the work of alien investigators

Of purely geographical exploration it is scarcely necessary to speak in this connexion, while the borderland researches of A. von le Coq, of Dr. Sven Hedin in Tibet, of Sir Aurel Stein in Chinese Turkestan, and of Koslov in Mongolia, are too well known to need more than passing mention. All

alike have played an important part in opening up China and the adjacent lands to the knowledge of the western world, have revealed their great stores of archæological riches, and have helped to attract the attention of scientific workers to Central and Eastern Asia as a fruitful and profitable field of Nor is it necessary to do more than refer research to the recent work of Shirokogoroff on the physical anthropology and culture of China. But China hasnow assumed a position of significance in palæontological and anthropological studies in a broader sense, and granted the continuation of exploration. may contribute evidence of the greatest importance for the problem of the origin of man and the de velopment and distribution of his early culture The sensational discovery of the eggs of the dinosaur by the expedition of the American Museum of Natural History has overshadowed the less striking but perhaps no less valuable archæological data collected by that expedition which related to early man m the stone age and the early ages of metal  $ilde{ ilde{1}}$ this area. Equally valuable and stimulating hav been the researches of P Licent and P Teilhard du Chardin, whose investigations have brought to light stone implements of types analogous to those of the Palæolithic age in western Europe in conditions which apparently place it beyond question that the geological evidence assures the quaternary date

The discovery of evidence for quaternary man \* China is of first-rate importance, but its interest has since been greatly enhanced by the discovery of teeth, claimed to be human or sub-human, a Chou Kou Tien, and estimated to be contemporar with Piltdown man. This in turn would le' support to the human origin attributed to fossi. teeth of primitive type bought in Peking some years ago. Coming to a later period, a discovery of the greatest interest arose from the excavation of sites of neolithic culture in Honan and Fengtien on which there occurred painted pottery similar is technique and decoration to that which has been found in the early archæological strata of Western Asia, Mesopotamia, Anau, Susa, and other sites. Although the question of dating still remains open this discovery links up with a series of sporadi finds stretching across Asia and appears to brii China into some sort of relationship, still to ' defined, with the west at an early date

These results have been achieved through th labours of non-Chinese men of science, and withouthe active co-operation of the Chinese themselve although those who have been responsible for a results acknowledge that in most part they have

ceived full and courteous consideration at their hands. But many difficulties have been encountered. This must be taken neither as a criticism nor an attribution of blame. The difficulties were in part financial, in part due to a failure to appreciate the opportunities for research in this field, even when pointed out. That China now assumes a place of importance in the study of early prehistory is due almost entirely to Dr. J. C. Andersson, the Swedish investigator, who acts as mining adviser to the Chinese Government. By his own work, in directing and inspiring the work of others, and by raising funds for publication, he has made prehistoric China known to the world.

There is an interesting parallel in the occasion for the protests which have been raised both in Egypt and in China In the former case the Egyptians viewed with apprehension the opening up by foreigners of the richest tomb ever found, of which part of the contents at least were to leave the country; the Chinese were aroused by the almost fabulous but entirely fortuitous monetary value attributed to the dinosaur's eggs. In these two instances the circumstances were exceptional, but there is a principle involved which is the crux of international participation in research in which the results are, to a very considerable degree both material and limited in extent No country which has become scientifically self-conscious can view with equanimity the danger that it may be despoiled of its scientific treasures by foreigners, and there is grave danger, unless some equitable arrangement is devised, that this may extend from the collection and exportation of specimens and objects of scientific interest to all prosecution of research in the field by others than natives Something of this feeling is to be discerned in India and Egypt . it appears to be a danger in China It may, perhaps in present conditions inevitably will, crop up in countries in which archæological research is now being conducted under the auspices of a protecting or mandatory power, such as in Mesopotamia That day may still be distant and Palestme

Even countries intellectually advanced are not entirely free from this spirit, and we have on more than one occasion raised a protest against the grant of exclusive concessions for archæological excavation to a single nationality, as for example in Albania and Afghanistan. Again, where the problem of international co-operation has in part been solved by the establishment of archæological schools as in Greece, the number of excavations which may be undertaken by any single school tends to become more strictly limited.

It is impossible not to sympathise with the attitude of those who feel that scientific material, and particularly the evidences of the past history of their country, should not be reft from them by outsiders, especially by mere collectors. A historical site when once turned over by the excavator can never be restored, be he competent or the rever-e Archæological material taken from the country will never be returned. It is to the interest of science itself that a government should claim the right of control through permits and concessions, if only as a safeguard against the incompetent investigator, but much more may be demanded and it is difficult to see where to draw Scientific research in these fields is worldwide in its bearing, and restriction in any one area hampers progress in the whole in the study of the broad problems of origin, development, and distribution Investigation should therefore be undertaken by the best man available at the moment, irrespective of nationality. The results should be made accessible to all by the exhibition of series characteristic of the objects found in museums. readily accessible to the great intellectual centres of the world and by early and detailed publication of the descriptive matter relating to the site or find. How best to reconcile the conflicting interests is a problem for which a solution will have to be found, possibly as a result of some international agreement through machinery such as the League of Nations may afford.

### Science in the Public Services.

The Ministry of Agriculture and Fisheries. By Sir Francis L C Floud (The Whitehall Series.)

Pp x+330 (London and New York G P Putnam's Sons, 1927) 7s. 6d. net

THE Ministry of Agriculture and Fisheries is one of the newer departments of the State. though it only obtained its designation as a Ministry in 1919, it was founded in 1889 as the Board of Agriculture, and took over certain functions which had previously been administered by the Privy Council. Later Acts have extended its interests and powers, but it remains unique among departments of State in Great Britain in that it deals with a special section of the community rather than a particular function of government

The Ministry is concerned with legal and land questions, with statistics, education, research, and labour, but only as they affect farmers and farming, and independently of other departments like the Board of Education which deal generally with one of these matters As the author of this book says at the outset, 'Agriculture and Fisheries are the only industries which have a Cabinet Minister of their own to represent them in the Government" If on one hand this gives a singular unity of purpose to the department, on the other it is the source of constant trials, both to its ministers and officials The industry of agriculture is not unnaturally disposed to regard the Ministry as its own special servant and the minister as its advocate. No other office is so permeated by a public seeking assistance or redress, no other minister is so subjected to advice and admonition. The Minister of Agriculture is indeed allowed but little respite from criticism, and he must not expect any compensation in the way of support from the farmers he represents This may in part explain the fact that from 1914 onwards there have been eleven ministers of agriculture.

The book before us is the work of the recently translated Permanent Secretary of the Ministry, Sir Francis Floud, a man who writes with authority, not only because of his familiarity with every detail of its work but also because of the singular trust and affection that his administration has inspired. The book sets out lucidly and with precision the services rendered by each division of the Ministry, the powers with which it is endowed, and the regulations it is called upon to enforce.

These functions are many and various. On the legal side the Ministry used to determine the tithe rent charge, and is still responsible for redemptions, it is the guardian of common lands, their regulation and possible enclosure; and it is the custodian of the corporate estates of the universities and colleges of Oxford, Cambridge, and Durham, and of Winchester and Eton It controls the acquisition of land for small-holdings and allotments, it has other controls to administer, such as those concerned with certain diseases of animals and plants, with rats and mice and weeds, and with the sale of seeds, fertilisers, and feeding-stuffs. Ministry is further responsible for the expenditure on agricultural education and research in England and Wales. The Fisheries Division is a separate department in petto with its own local authorities to deal with—the fishery boards—its own functions of control over fishing and fishermen, its own research to foster and its own statistics to collect. Kew Gardens and the Ordnance Survey are other self-contained organisations for which the Ministry is ultimately responsible

As regards many of these functions, however, and those the more important, the Ministry is less

the actual executive than the administrative bod. which lays down conditions and defrays, wholly or in part, expenditure incurred by other authorities charged with the execution of the work example, the maintenance of educational agencies like the agricultural colleges and the farm institutes depends chiefly upon funds supplied by the Ministry, but the management of these institutions rests with the universities and kindred bodies, or the local authorities. Again, the research institutes, which are largely founded and supported by the Ministry, are under the control of a university or independent governing body, and their officers, even though their rates of pay are determined by the Ministry, are in no sense civil servants research, as regards fisheries alone is this principle of delegation departed from, for the Ministry's veterinary laboratory and its phyto-pathological laboratory are concerned only with such investigations as may affect the administration of the department

It will be seen that the work of the Ministry is largely of a technical character, and, as Sir Francis Floud states, "the work of the Ministry could not be carried out without the employment of a large number of specialist officers, whose work, though different in character, is just as important as that of the administrative or clerical staff." Sir Francis admits the equal importance of the technical officer, and has always acted on that view, but none the less the system of the office permits of no scientific specialist rising to the rank or pay of an assistant secretary, except the chief vetermary officer. In his view the executive should—

"enlist men who have received a good general education in the schools and universities and give them a thorough training in the routine of a Government Department" "It is far better that the ordinary staff of the Department should make no pretensions to be experts. The important thing is that they should have open and adaptable minds, and the capacity to exercise a sound judgment on the advice or proposals, often divergent and contradictory, which come before them from the experts and the practical men of the industry. There is a distinct technique of administration which must be learnt, and it must be combined with a sense of proportion and a recognition of political, financial, and practical limitations with which the specialist is often impatient."

The case for the subordination of the scientific officer could not be better put, and it emphasises the fact that in the higher ranks, whether it be of a government office or a business, it is the administrative faculty that is the essential, besides which nothing else counts But the advocates of

this traditionally English view have never explained why administrative ability is incompatible with technical knowledge. Men have to be judged as men, and if the irresponsible specialist is apt to be too absolute in his dicta. Government departments are not unfamiliar with the pseudo-administrator whose art is to put a smooth face on things and to anticipate the jumping of the cat

Though the made 'expert' can rarely be brought in to take over the complex routine of governmental administration, it should be open to the young scientific officer who enters the service as a specialist to pass over to the executive and be placed later in the running for the higher offices, but only as he shows himself capable of that type of work. The ideal administrator will possess a critical background of technical knowledge Its absence matters little while departments are mainly regulatory, but as they become increasingly constructive, and the Ministry of Agriculture has had to move in that direction, the need for combining both types of mind will become insistent. Yet the prospects of scientific men in government service are not improving. The Ministry of Agriculture has enjoyed since the War a scientific staff in which the industry has confidence, and a feature of Sir Francis Floud's administration was the sympathetic understanding with which he used it. But it may be doubted whether such a staff can be repeated, so limited are the opportunities likely to be under the alien Civil Service tradition and the pressure on promotion boards of Whitley Councils in which the clerical element dominates.

### The Natural History of Ornithorhynchus.

The Platypus: its Discovery, Zoological Position, Form and Characteristics, Habits, Life History, etc. By Harry Burrell. Pp. ix +227 + 35 plates. (Sydney, N.S.W.: Angus and Robertson, Ltd.; London: The Australian Book Co., 1927.) 25s. S its amplified title indicates, this work does not set out to be a systematic descriptive scientific treatise on Ornsthorhynchus anatonus. It is true that it necessarily includes incidentally a good deal in the way of the morphology and physiology of the animal, but it is entirely in accord with the scheme of the author that detail appropriate to a more academic and systematic treatment of structure and function should be either omitted or subordinated to his main purpose. The book is pre-eminently the product of a genuine field naturalist—a type unfortunately less common

than it used to be—an amateur, in the proper and literal sense of a devoted lover of the animals he knows so well.

His book, as Mr. Burrell informs us, 'is the result of nearly twenty years' personal observation of the Platypus in its haunts while collecting specimens for the University of Sydney and the Commonwealth National Museum' Without any disparagement of earlier contributions to the natural history of the monotremes from the beginning of the nineteenth century onwards, and including those resulting from the special expeditions of Caldwell and Semon, it may safely be said that no such complete story of the life history, habits, and behaviour of Ornithorhynchus has ever been presented as that we have now before us in Mr. Burrell's admirably illustrated pages

The author speaks regretfully of the hindrances to his work occasioned by administrative regulations. Surely some easy mean might be discovered between the former extreme of total neglect of the problem of protection of fauna of such singular interest and scientific importance, and the more recent extreme of a well-nigh indiscriminating prohibition of collecting even for disinterested scientific purposes. Is it too much to hope that the recently organised Commonwealth Bureau of Scientific and Industrial Research may be empowered to exercise a wisely advisory function in the regulation of local scientific activities of this nature, whether conducted by Australian or extra-Australian agencies?

Meanwhile, one can only admire the tenacity with which Mr. Burrell has pursued his task in spite of all obstacles, and gratefully welcome the very substantial contribution he has been able to make to the natural history of the archaic mammal the intimate life of which he has so successfully investigated. Only those, perhaps, who, like the present writer, have themselves essayed the pursuit of the same difficult quest, both personally and by proxy, can adequately realise what that tenacity and that success really mean

The earlier chapters of the work before us, dealing with the discovery and early descriptions and with the former controversies on the zoological position and the oviparous character of the animal, are of slighter importance to the present-day zoologist. Yet they do, no doubt, provide a useful résumé for the non-scientific reader, especially in Australia, of the growth of knowledge concerning an animal the unique features of which have all along presented a problem of unusual interest.

Chapters v.-vii, on general characteristics, on

nervous organisation and sensory perceptions, and on the spur and crural gland, contain a good deal of useful information, much of which is from firsthand observation—the last of these sections, however, seems unnecessarily diffuse

It is the latter half of the book, from Chap, vni onwards, which will more especially engross the interest of the student of natural history. Chap viii treats at considerable length of the elaborate nesting burrow and its construction. On this subject the author can speak with the knowledge and authority derived from long, laborious, and fruitful investigation. The value of his account is also greatly enhanced by an admirable series of photographic illustrations.

Chapters ix. and x are concerned with the general habits, food, and domestic economy of the animal. Chap. xi. will perhaps most of all attract the attention of the zoologist. In it are set forth Mr Burrell's original observations on mating, egglaying, hatching, and the growth of the young to adolescence. How well qualified the author is to contribute to our knowledge of these matters may be inferred from his record of personal observation of no fewer than seventy tenanted nests. Here again his statements are supported by a number of excellent photographic illustrations, amongst which those showing twin and triplet nestlings in their nests are specially noteworthy.

The final chapters deal with the subjects of 'preservation and economics,' and with that of the Platypus in captivity. It is no small achievement to have succeeded in keeping alive under observation and in good condition for months at a time, specimens of an animal so delicately adapted to its own natural conditions as Ornithorhynchus.

In the way of actual criticism, it may perhaps be said that when Mr. Burrell does descend to the discussion of morphological or physiological details, he is on less sure ground. Thus, for example, it cannot be admitted that (p. 67) the olfactory nerves are "relatively large" in a mammal that has by some authorities been classified (albeit with insufficient justification) as actually 'microsmatic.' In this connexion, too, one might have expected some reference to be made to that still enigmatical olfactory dependency, the vomero-nasal organ of Jacobson, which in Ornithorhynchus is of such imposing and well-nigh reptilian proportions and is almost, if not quite, the largest amongst mammals. To the nerves connected with this quasi-olfactory apparatus the apparent 'olfactory' nerve owes a fair share of its own quite modest proportions. It is searcely too much to say that the discussion of the organs of sensory perception as a whole is weak and sketchy. The reference on p. 70 to the lateral line organs of fishes betrays a misconception of their real function. It is to be hoped that in any subsequent issue the reference, in Plate 3, to the openings of the naso-palatine canals as the 'nostrils' will be corrected, as well as the misleading legend 'jawbones' in Plate 4

The bibliography at the end of the book is clearly in no sense a bibliography of Ornithorhynchus Presumably it is meant to refer only to the topics dealt with in the book itself But even in this sense it is far from complete. Although in Chap. vi a slight attempt is made to deal with brain characters, no references are given even to the most important literature on this branch of the subject, including the work of Turner, Elliot Smith, and Ziehen Agam, whilst the characters of the snout or muzzle are correctly insisted on in the chapter on general characteristics, no reference is given to controversy on this subject in 1894 (cf. Proc. Linn. Soc N.S W, vol. 9, Ser. 2, p 688).

Any minor faults of omission and commission which the book may show are amply atoned for by its conspicuous merits in the direction of the author's authentic interest. Judged by its own proper criteria, Mr. Burrell's book must be pronounced to be a contribution of considerable value to the literature of the natural history of the Mammalia, a testimony to the industry and enthusiasm of its author, and a credit also to its enterprising Australian publishers

J. T. W.

### A Persian Oil Field.

In a Persian Oil Field: a Study in Scientific and Industrial Development By J W. Williamson
Pp. 189+24 plates. (London: Ernest Benn, Ltd., 1927.) 7s. 6d net

HE Tigris and Euphrates jom north-west of Basrah and thence flow to the Persian Gulf as the broad, silt-filled stream known as the Shatt-el-Arab. For some hundred miles the combined rivers wind their way between low banks of alluvium, on which, except for the small areas cultivated around the Arab villages, nothing of value grows save the date palm. The scene and the surrounding country have probably been much the same for the past two thousand years, although evidences of Roman irrigation works indicate that, at one time, vast areas of the country must have been under effective cultivation and have remained so until the system, lapsing into disrepair, enabled the highly charged waters of the two rivers again to impreg-

nate the soil with mineral salts so as to render it productive of little but the camel thorn

If conditions are favourable, a traveller on the mail-boat from Bombay usually passes the bar at the mouth of the Shatt-el-Arab during the evening. and for the next few hours steams up the river between dark and inhospitable banks Suddenly in the far distant sky a blaze of light is reflected and the ship passes a veritable town-hip brilliantly illuminated and teeming with industrial life. Thereafter, until Basrah is reached, there is again nothing but the blackness of the unmhabited desert contrast is so great that the traveller finds it difficult to believe that twenty years ago this township was also part of the desert and that it was here that the first pioneers, many of whom are still active in the Company's service, started to build the piers and jetties from which at the present time a large proportion of the oil is transported to the home refineries at Llandarcy and Grangemouth it was here, at Abadan, that the Anglo-Persian Oil Company decided to build its refinery and loading station at the head of the pipe lines which carry the crude oil from the 'Fields' some 150 miles distant northward across the desert

The book under review contains a description of the country developed by the Company, and is the outcome of a visit paid by the author during the cold weather of 1926. It is divided into two sections—Part I. "The Science," and Part II. "The Humanities"—and constitutes a striking record of British mitiation and achievement which is good to read.

Although the author disclaims any intention of producing a technical book, yet it is evident that his wide knowledge of general science has enabled him to impart to Part I. of his book a breadth of view and of sympathetic treatment which throws the policy of the Company in regard to the development of the scientific side of its activities into strong The scientific problems of the Persian oil field are unique, and can be solved only by systematic research in which the chemist and physicist must combine to help the geologist and engineer. Much has been achieved, but much remains still to It is evident from the author's record be done · that great and successful efforts are being made to meet the inherent difficulties of the situation

For one who has had an opportunity of visiting the places he describes, it is of particular interest to note the able manner in which the author takes the reader by the hand and leads him through the various phases of oil production, beguiling him with pleasant but instructive conversation by the way, yet refraining from satiating him by the glib talk of

millions—for statistics, however veracious, are apt to produce a state of repletion from which the ordinary reader usually emerges in a condition of static disbelief

Part II . dealing with "The Humanities," records a system which any industrial organisation might follow with advantage to itself and its workers. It describes the means adopted by the Company to render the lot of its European staff pleasant and congenial. An account is also given of the housing and care of the native worker, and of the means taken to educate his children. Above all, attention should be directed to the description of the admirable medical service, which, under the care of the medical directorate, has reached a degree of efficiency probably without parallel

The illustrations of which there are a large number, are excellent and are very clearly reproduced. Without question, the author is to be congratulated on having produced a thoroughly readable volume which places on record, in a manner understandable by all, an epic of achievement of which all Britons must be proud.

JOCELYN THORPE.

### Maxwell's Scientific Papers.

The Scientific Papers of James Clerk Maxwell Edited by W. D. Niven. (Photographic Reprint by arrangement with the Cambridge University Press) Vol 1. Pp xxxii+607. Vol. 2. Pp. viii+806 (Paris. J. Hermann 1927) 3 livres 6.

T is not often that a reissue of the collected papers of an outstanding scientific man has been called for. Some of the papers cannot fail to have historical value because of the part which their original publication played in the development of science. but that value alone would not be sufficient to secure the demand The work involved must be of present-day importance. Therefore its consequences must still be in process of development, and it follows that if, as in the present case, the republication follows the first publication after an interval of half a century, the mam papers involved must have been of very epoch-making type. The condition of present value is a sufficient test; but the most essential condition is that of permanent value. Present value persisting after the lapse of fifty years suggests permanence, and at least points to some enduring quality—the direct impress of the distinctive personality of the man.

How much might be attainable in that way was made clear at the threshold of Maxwell's scientific life when it was said of him by his Cambridge tutor that it seemed to be impossible for him to think wrongly on a physical subject. How much had been attained in its brief duration was perhaps most impressively made evident by the incident of the entry into a railway carriage at a Dumfriesshire station of a countryman who took his seat with the single remark, "Maxwell is dead"

It may be sufficient to refer, in illustration merely, to the three main lines of investigation which are dealt with in the papers In the subject of colour vision, the work of the man who, simultaneously with and independently of Helmholtz, introduced for the first time methods of precision into a previously vague field of inquiry, is still of value to a multitude of workers; for he dealt with the best methods which could be used In the subject of the electromagnetic field and its properties, the results of his epoch-making inclusion of optical phenomena are of fundamental importance in the now pressing investigation of the state of ionisation of the upper atmosphere. Experience has verified the soundness of his judgment regarding the form of the equations of the field; and new discovery regarding electrons has led to the natural extension of the equations, on his own lines, by the recognition of electric currents of convection. In the subject of molecular theory, his work has recently been finding its verification alike in the field of things smaller than atoms, whereof knowledge had not reached him, and in the field of a stellar universe wherein the atoms are suns. This is an interesting astronomical reversion if his molecular investigations arose in connexion with his work on the rings of Saturn.

The student who desires to follow Schrodinger in his endeavour continuously to bridge the gaps indicated by the modern atomic and quantum postulates and to restore to the physicist the Maxwellian ether, of which some relativists thought they had deprived him, could not do better than read as a preliminary the papers in which Maxwell applies the Hamiltonian characteristic function to the solution of some optical problems. In the perusal of any of the papers the student will learn something of the mode of working of the mind of one who was a master amongst masters. It is not possible for a student to make too much use, in that way, of the works of the great thinkers. Thereby he may at least train himself to heighten the value of whatever work he does.

To the Cambridge University Press and to the firm of J. Hermann are due the thanks of physicists for the completion of a greatly needed reissue. The quality of the photographic work, and of the general technique, is high.

### Our Bookshelf.

Bauxite a Treatise discussing in Detail the Origin, Constitution, known Occurrences, and Commercial Uses of Bauxite: and including Particulars regarding the Present Condition of the Aluminium Industry and the Peculiar Importance of Cryolite in the Extraction of Aluminium from Bauxite By Dr Cyril S Fox. Pp x+312. (London: Crosby Lockwood and Son, 1927) 30s net.

With the increasing popularity of the metal aluminum, increasing interest is being taken in its principal ore, bauxite, and Dr Fox has opportunely provided a trustworthy and comprehensive treatise on the occurrence and uses of this substance. He distinguishes two principal modes of origin, the terra rosa (sic) type representing the insoluble residue of great masses of soluble limestone or dolomite, and the lateritic type resulting from the decomposition in situ of original aluminous rock. The former occurs mainly in the Mediterranean region of Europe, and the latter in the tropical monsoon lands of Asia, Africa, and America.

The largest known reserves of ore are of the lateritic type, and the author's descriptions of typical occurrences are of great interest and value. There will be general agreement with his conclusion that lateritic bauxite and lateritic ironstone stand at opposite ends of a series of tropical decomposi tion products, of which true laterite with, theoretically, equal quantities of hydrated ferric oxide and trihydrate of alumina occupies the middle. Dr. Fox gives a useful summary of current opinion upon the nature of the process of lateritic weathering in the tropics, and suggests a number of conditions which seem to him necessary for the formation of laterite. The economic aspects of the bauxite and aluminium industries are discussed in considerable detail and supported by statistical information The book is well printed and well illustrated, and the author is to be congratulated on producing: work which meets a pressing need of the day

Modern Bee-Keeping. By Herbert Mace. Pp. 225 +xix+16 plates. (Harlow, Essex The Publisher, Modern Bee-Keeping, 1927) 5s. net.

HAVING chosen such a title as that of "Modern Bee-Keeping," the author might be expected to show familiarity both with modern apicultural practice and also with the recently ascertained facts of science. He repeats, however, without comment, the old statement that Braula cæca is pupiparous, even though the egg and larva have been figured by several observers, and the damage done by the larval tunnels in the cappings of honey has actually been illustrated in an English-speaking bee journal.

Agam, the old theory that the brood food is regurgitated chyle is given here as an undisputed fact, whereas the opposing view that it is a secretion of the lateral pharyngeal glands is the one more generally held at the present time. Referring to races, the author confounds the brown German bee of pre-Isle-of-Wight days (Apis mellifica L.) with

the black heath bee (Apis mellifica var Lehzeni) of Holland and parts of France

In the chapters on disease, much confusion of thought as to etiology and causative organisms is shown, both in referring to brood diseases and also diseases of the adult bee, which are all brought together under the term. Isle of Wight Disease." Remedial measures are given, sometimes without making it clear for which disease they are intended, and without insisting that a correct diagnosis is necessary before prescribing

It would be easy to continue to criticise the scientific part of the book, and the same could be done with the part dealing with practical methods, but here we are dealing with matters of opinion. Suffice it to say that many of the operations should be condemned as being calculated to spread bee diseases rapidly through the apiary.

D. M.

The General Theory of Thermodynamics: an Introduction to the Study of Thermodynamics. By Prof J E Trevor Pp. x+104 (Boston, New York, Chicago and London Ginn and Co., Ltd., 1927.) 1 60 dollars

THE object of Prof. Trevor's book is to "develop the general laws of Thermodynamics with logical consecutiveness and mathematical clarity for students of physics, physical chemistry and engineering, for mathematicians and practising engineers. No applications of general principles are considered. The treatment departs considerably from traditional lines, as would be expected from the author's paper in the Journal of Physical from the author's paper in the Journal of Physical . Chemistry, 1908, and familiar words and phrases are used in new and disconcerting senses. Thus when a weight w is raised a small distance dh, "the inexact expression wdh denotes the work absorbed " (p 12). The equation dE = dW + dQ "asserts that the work and heat absorbed are integrals of exact differential expressions" (p. 13) In connexion with the pv diagram, "an irreversible path cannot be depicted by a curve in the plane "(p. 18). The law of dissipation runs, "when a thermally and dynamically isolated body undergoes a change of state that admits of a reversible path, the change of the entropy of the body is positive "(p. 85), which appears unduly restrictive. In later chapters, for example, that on the porous plug experiment, the treatment conforms more to tradition. It is not easy to understand how the book can serve as "an introduction to the study of thermodynamics.

Memoirs of the Geological Survey of England and Wales Explanation of Sheet 232: The Geology of the South Wales Coalfield. Part 2: Abergavenny By Aubrey Strahan and Walcot Gibson, with Notes by J. R. Dakyns and Prof. W. W. Watts. Second edition, by Dr. T. Robertson. Pp. x1+145+4 plates. (London: H.M. Stationery Office; Southampton: Ordnance Survey Office, 1927.) 3s 6d. net.

The first edition of this important memoir was published in 1900,  $\varepsilon$  d the need for a new edition has been made the coasion of certain additions and corrections, none of which can, however, be said

to be of any serious importance. A good deal of palæontological work has been done, especially perhaps in the Millstone Grit. Naturally, the active development of the colheries during the last quarter of a century has thrown valuable light upon the structure of the coalfield. The Carboniferous Limestone has been exhaustively studied and the question of its dolomitisation has been examined in detail. The fact that a quarter of a century of active work has necessitated so little change in any of the fundamental portions of the memoir is evidence of the care and thoroughness with which the work was originally done.

Soil Conditions and Plant Growth. By Sir John Russell (The Rothamsted Monographs on Agricultural Science.) Fifth edition. Pp viii + 516+6 plates (London Longmans, Green and Co., Ltd., 1927.) 18s. net.

This well-known text-book has now reached its fifth edition, a sufficient proof of its value and The last edition has been revised in popularity the light of the author's recent travels abroad, during which he has had many opportunities of seeing the work of other stations. Nevertheless, the book retains its original character, and continues to give great (and no doubt well-merited) prominence to the work of Rothamsted. recent years that has been largely concerned with soil biology in what may be loosely termed its purer aspects, but the agronomist feels that field results have followed slowly and is glad that soil tillage—which exercises a profound influence on the soil flora and fauna—is now engaging the serious attention of Rothamsted. We doubt also whether sufficient prominence has been given to the work of other soil laboratories, such as Bangor The recent revolution in the methods of soil analysis, as referred to in App. I., for example, is due entirely to the original work carried out there.

Some Nigerian Fertility Cults By P. Amaury Talbot. Pp. xi+140+16 plates. (London. Oxford University Press, 1927) 12s. 6d net

Mr. AMAURY TALBOT here describes the beliefs of the Ibo and Ijaro tribes of the Degamo division to which he was posted in 1914 For the most part they centre around the cult of Ale, the Mother-Earth goddess, and her consort, the Thunderer. Mr. Talbot describes at some length the M'bari houses or shrines and the ceremonies connected with them. He has brought considerable acumen to bear on the interpretation of these rites; but perhaps his most pregnant suggestion is made in connexion with the cult of the Great Drum. By an ingenious line of reasoning, he unravels the symbolism of the representation of the tortoise and identifies it with the female pudenda. Of the many ceremonies and beliefs connected with the promotion of the fertility of the crops which serve to illustrate the principles of the "Golden Bough," the most striking is that relating to the priest of the Elele Yam cult, whose office, like that of the priest of Nemi, reverted to the man who succeeded in slaying him.

### Letters to the Editor.

## The Diffraction of Cathode Rays by Thin Films of Platinum.

In a letter to NATURE of June 18, Mr Reid and I described the rings formed when a beam of cathode rays was sent at normal incidence through a thin film of celluloid and struck a photograph plate placed some distance behind the film These were attributed to a diffraction of the cathode rays by the film, the cathode rays behaving as waves of wave-length himv according to de Broglie's theory of wave mechanics, and regularities in the structure of the film, or in the size of the molecules, making it behave as a kind of In a paper now awaiting publicadiffraction grating tion by the Royal Society, this work has been confirmed and extended to films of gold, aluminium, and of an unknown (probably organic) substance. In particular, the relation that the size of the rings is in all cases inversely as the momentum of the cathode rays is fully confirmed, and the number and size of the rings correspond remarkably with what is to be expected from the known crystalline structure of gold and aluminium, using de Broglie's expression for the wavelength of the cathode rays.

The present letter describes an extension of these results to the case of platinum. The difficulty was to get a film of platinum sufficiently thin to permit of the passage of the cathode rays without so much scattering as to mask the rings. One method was to obtain a thin film of platinum by cathodic spluttering on glass and removing the deposit by hydrochloric acid. This gives films thin enough to be transparent and several millimetres each way, but when they were mounted on frames, they always broke during the course of drying. To avoid this. I tried mounting them on the thin celluloid films used in the earlier experiments. This, of course, has the disadvantage that one would expect to get the rings due to both celluloid and platinum superposed. However, the most marked celluloid ring is about half the size to be expected for the smallest platinum ring, the other celluloid rings being very faint, under the conditions of experiment. It was found that when a photograph taken with platinum on celluloid was compared with one for celluloid alone, several new rings appeared. The photograph (Fig. 1) shows the innermost and strongest of these, the celluloid ring inside being visible only as a disc owing to over-exposure. In addition there were two new outer rings too faint to reproduce. Photographs were taken of these rings with various speeds of rays, and the size varied inversely as the momentum within the errors of experiment.

Since platinum is a face-centred cube of side  $3.91 \times 10^{-8}$ , the distances d between successive crystal planes are given by  $\frac{3.91 \times 10^{-8}}{\sqrt{h^2 + k^2 - l^2}}$ , where h, k, l

are the indices of the plane, to be so chosen that they are all even or all odd. The smallest values of the denominator are  $\sqrt{3}$ ,  $\sqrt{4}$ ,  $\sqrt{8}$ ,  $\sqrt{11}$ ,  $\sqrt{12}$ . Each of these spacings gives a ring in the Debye-Scherrer method of X-ray analysis, and if the view that all particles behave like waves is correct, should do so with cathode rays also, assuming that small crystals orientated at all possible angles to the beam are present in the film. It is believed that the ring illus-

trated is a compound of the  $\sqrt{3}$  and  $\sqrt{4}$  ring unresolved (in the case of gold, which gives better films, the corresponding rings have actually been resolved), the two outer rings being  $\sqrt{8}$  and an unresolved compound of  $\sqrt{12}$  and  $\sqrt{11}$ . Taking the diameter of the inner ring as the mean of  $\sqrt{3}$  and  $\sqrt{4}$ , the diameters of the outer rings are  $\sqrt{8}$  2 and  $\sqrt{11}$  1 as a mean from four plates. The absolute size of the rings is given by the Bragg law  $n\lambda = 2d \sin \theta$ . Taking the inner ring and using the above formula for  $\lambda$ , I find for the side of unit cube 3.75 × 10-8 (mean of 6 plates) against 3.91 × 10-8 as found by X-rays. This is 4 per cent. low, and would be about 6 per cent. low if the

relativity correction were put in The values found for gold and aluminium were also low by about the same amount This may be due to a systematic experimental error, or may have a theoretical reason (for example, be analogous to the Compton effect) These results

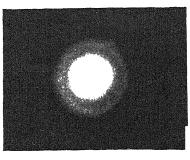

Fig 1.

have been confirmed by some experiments with a thin piece of platinum further reduced in aqua regia. Though this was still too thick as a whole, it must have had thin patches, as photographs showed, besides spots due to holes and the direct beam, other 'diffracted' spots airanged in circles round the centre. These are explained by supposing that in this film, which had probably been originally made by rolling, the crystals were not situated in all possible directions, and so did not give complete Debye-Scherrer rings, but only spots on them, more like a Laue pattern. It was possible to distinguish between the spots corresponding to the two inner rings, and the ratios of their distances from the centre were  $\sqrt{3} \cdot \sqrt{4\cdot 2}$  (mean of two plates).

The energy of the rays used in these experiments varied from 30,000 to 60,000 volts, and the distance from film to plate was 32 5 cm G. P. Thomson.

University of Aberdeen, Nov. 17.

Note added in proof.—Using a very thin piece of platinum leaf, I have now been able to obtain rings similar to those described above, without the use of celluloid backing. The inner ring is resolved into two as in the case of gold.

### Method of Fossilisation of an Insect Wing.

In has long been known that when the wing of an insect becomes fossilised the original chitin is either completely destroyed or else replaced by some other substance, such as carbon, silica, or oxide of from This, however, does not explain the extraordinary perfection with which some insect wings have been preserved, even in Palæozoic strata. A recent study of two thousand fossil insects from the Lower Permian of Kansas, approximately two hundred milhons of years old, has brought to light many specimens in which the wings are as perfect as if they had just been dissected from the insect, yet it is evident that three original chitin is not present, neither is it replaced by any other substance. The explanation of this is to be found as follows:

The wing of an insect is really a bag the sides of which have been brought into contact and fused together

except along the vein-channels. Thus there is an upper side formed of one layer of chitin, and an under side formed of a second layer in contact with the flist. The chætotary, or armature of hairs, is usually different on these two layers. Now, when a geologist flinds a rock specimen containing an insect wing, he may, if he is lucky, succeed in splitting it with a blow of the hammer in such a way that he obtains two perfect impressions, these are called the obverse, in which convex veins appear convex in the impression, and concave veins concave, and the reverse, in which convex veins appear concave, and vice versa.

A little consideration will show that it we took impressions of the upper and under surfaces of the wing of a recently killed insect, in dental wax or pla-ticine, it would be the upper surface which would give the reverse impression and the under surface the obverse impression. Now, in the Kansas fossils there are many in which both impressions are preserved perfectly, with colour-pattern complete. This is par-

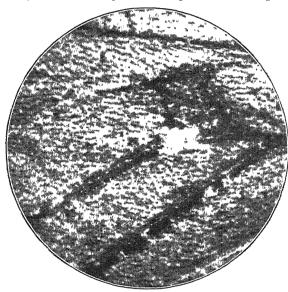

Fig 1—Lemmatophora tupuca Sellards, ramily Lemmatophoride, order Protoperlaria, Lower Permian of Kansas, U.S.A. Portion of reverse impression (upper surface) of foreving, showing the chartotaxy of numerous microtrichia. (Much enlarged)

Photo by W. C. Davies, Curator, Cawthron Institute

ticularly true of the fine species Lemmatophora typica Sell., already figured in NATURE (June 12, 1926, Fig. 2), and typical of the extinct order Protoperlaria, ancestral to our recent Perlana or Stone-flies accompanying illustration (Fig. 1) shows a small portion of the reverse impression, greatly magnified, from the region of the cubital fork of the following. The chætotaxy consists of an immense number of inmute hairs or inicrotrichia, resembling those of recent Perlaria, but somewhat stouter and shorter. This armature of fine hairs, then, must have been originally on the upper side of the wing in the living insect It, however, we examine an obverse impression from the same species, we find much smaller and more slender microtrichia present, together with a row of strong spines along the costal margin (evidently of use in preventing the forewing from folding too far back over the hind in the position of rest).

Thus we see definitely, for the first time, that the two impressions on the rock are actually the separate impressions of upper and under surfaces of the wing, and that they are separated by the exceedingly slight but measurable space represented by the thickness of the disintegrated chirm of the wing. The reason

why the impressions are so perfect appears to be, not only that the grain of the rock is so fine that even the timest hair has left its impression, but also because the pigments of the wing, unlike the chitin, have proved indestructible, and are actually preserved on the rock, even in the case of the timest coloured hair! That this is so can be simply demonstrated by exposing one of the coloured fossils to bright similght, when it will be found to fade markedly after a few hours only, just as the pigment in the wings of butterflies fades in museum cases exposed to the light.

R. J. TILLYARD.

Cawthron Institute, Nelson, N.Z., Sept. 21.

#### Abel's Pituitary Tartrate.

In 1919, Abel and Kubota isolated from the pituitary gland a single principle which they identified as (a) histamine, (b) the plain muscle-stimulating and depressor constituent. This conclusion, which they upheld in 1920 and withdrew in 1921, implied that the pressor constituent was not the plain musclestimulating (oxytocic) or the depressor substance. In 1923, Abel, Rouller, and Geiling prepared a tartrate from pituitary extracts 1250 times as active on the uterus as histamine and phosphate. This tartiate, they asserted, contains a 'single principle' responsible for the pressor, oxytocic, diuretic, and depressor activities. About the same time Hogben and Schlapp, studying the inversion effect, that is, the depression following a second injection of commercial extracts in the cat, found that with alcoholic extraction the depressor activity of their own preparations gave a diminishing depressor response, so that, with a powder made from glands put in icecold acetone immediately after killing, extraction for forty-eight hours resulted in a preparation which, with undiminished pressor activity, elicited no depressor action when administered in quantities equivalent to one hundred times the threshold for the pressor effect.

This was fully consonant with observations previously made by Schafer and Vincent, and with the properties of highly concentrated pressor fractions prepared by Dudley (1923), who in collaboration with Dale (1921) had advanced evidence indicative of the separate identity of the oxytocic and pressor substances. The work of the latter was confirmed independently first by Dreyer and Clark (1923) and later by Fenn (1924). Using a method of pressor assay designed by Hogben, Schlapp, and Macdonald to give an accuracy as great as that obtained with Dale's procedure for standardisation of the oxytocic principle, Schlapp (1925) conclusively proved the possibility of separating the two constituents by Dale and Dudley's method, that of Dreyer and Clark, and by a new procedure of his own. At the end of last year there appeared in *Physiological Reviews* a résumé of recent work on the pituitary gland from Abel's laboratory. In it Geiling maintained the validity of the claims of Abel and his co-workers to have concentrated a 'single principle' to which the manifold pharmacodynamic properties of pituitary extracts can be attributed Beyond the bare statement that Abel and his colleagues were not able to subscribe to Dale and Dudley's contention, no attempt was made to explain why several groups of workers had been successful in concentrating the pressor and oxytocic activities in separate fractions. With reference to the inversion effect, however, Geiling made the

"Unpublished experiments of the writer show clearly that even after a defatted pituitary powder has been extracted forty-eight hours in a Soxhlet with absolute

following pronouncement:

alcohol, as described by Hogben and Schlapp, it will still produce, when injected into etherised cats, either with mact or with cut vagi, and in the same doses as used by Hogben and Schlapp, a lessened response with the second injection, and later injections will effect the inversion. Hogben and Schlapp are in error, when they assert that the fall in pressure is due only to the depressor substance and is not an intrinsic property of the infundibular extract. (Italics inserted)

Owing to departure from the American continent, the present writer was prevented from replying at the time to this ex parte and undocumented statement in what one presumed to be an impartial survey of existing literature. Two subsequent publications, however, one by Vincent and Curtis (Endocrin, 10), and one by Draper (Am Jour. Physiol., 80), together with the text of Geiling's experiments (Geiling and Campbell, Jour. Pharm. Exper Ther, 29), now call for comment on the claims of Abel and his collaborators to have concentrated a 'single principle'

As regards Geiling and Campbell's experiments, it is to be noted that they admit having used a commercial preparation, and frankly state that "the outstanding feature of their experiments was the variability in the development of a depressor response." Their tracings show no saline controls, and, where an undoubted depressor effect is indicated, the dosage was much greater (five times) than that used by Hogben and Schlapp. they made no quantitative comparison of depressor activity during the progress of extraction, an essential point in the thesis of Hogben and Schlapp; and, finally, they seem to have obtained their very transient depressor effects by rapid injection of cold extract. It now appears from Vincent and Curtis's paper, which upholds the view that the depressor action of pitutary extracts is due to a separate substance, that rapid injection of cold salme can of itself produce the type of depression which Campbell and Geiling obtained.

Whatever be the truth with regard to this issue, there is now little room for doubt about the separate identity of the oxytocic and pressor substances. Draper (1927) has repeated Schlapp's work, using the improved method of pressor assay, and a method of diuretic standardisation devised by himself for the purpose. His observations, like Schlapp's, Fenn's, and those of Dreyer and Clark, confirm the view of Dale and Dudley. In addition, Draper directs attention to a point which, in view of the aggressive tone of Geiling's review, is worthy of quotation:

"A study of these data [i.e. those of Abel, Rouiller, and Geiling] reveals the fact that the three activities were not preserved in their original proportions. On the connot preserved in their original proportions. On the contrary a great loss of the pressor and duretic activities seems to have taken place. . . . 0 2 mg. of a tartrate having an oxytocic titer of 500 times histamine acid phosphate is shown to cause a slight rise of blood pressure in an anæsthetised cat, and 0.05 mg. is shown to produce a submaximal diuretic effect in an anæsthetised rabbit. These doses had the oxytocic activity of 100 mg. and 25 mg. of histamine acid phosphate respectively, and were the oxytocic equivalent of 100 cc. and 25 c.c. of the liquor hypophysis U.S.P. ix Since one tenth to one hundredth of a c.c. of liquor hypophysis is sufficient to raise the blood pressure of a cat and to promote diuresis in a rabbit, it is evident that these activities had been almost completely destroyed or eliminated in the process of purification.

In short, if Abel and his associates have evidence, as yet unpublished, to support Geiling's statement that "all the physiological properties of our active substance increase in intensity and in the same ratio parı passu," it is unfortunate that such data have been withheld from other groups of workers. The data they have placed at the disposal of other investi-

gators prove the very opposite If, on the other hand, no such data are available, one may hope that Abel will relinquish his claims to have concentrated a 'single principle' with the same candour as he displayed in withdrawing his previous view that the oxytocic and depressor substances were different from the pressor and identical with histainine.

LANCELOT HOGBEN.

University of Cape Town, Sept 1.

#### Oceanic Deeps and the Thickness of the Continents.

In a recent paper dealing in part with the structure of the lithosphere (Geological Magazine, June 1927) I assumed the substratum of the floor of the Pacific to be mainly eclogite, and I hinted at the possibility that the great bordering deeps of that ocean might mark the sites of great intrusions of peridotite. This speculation, however, fails to accord with the requirements of isostasy and is therefore unsatisfactory. An analysis made by Hiller (Gerlands Beitrage, 1927, p. 279) of the velocities of long waves which had followed widely different paths around the upper layers of the lithosphere seems, moreover, to rule out the identification of the Pacific sima with eclogite. For waves having a period of 18 to 20 seconds, Hiller finds velocities of 37 km. per sec. in the material of the Pacific floor, and 29 in that of Europe, Asia. and America. He adds that these are the respective velocities to be expected in sima and sial. Comparison of the ratio of these velocities (1 27) with that of the corresponding P- or S-wave velocities in gabbro and granite (1.23), indicates that the floor of the Pacific down to a depth of the same order as that of the sial of the continents behaves as gabbro would do

If this identification be adopted, a reasonable explanation can be offered to account for some of the more puzzling features of the oceanic deeps. The effect of intense compression on a thick floor of gabbro would be, not to produce mountains or submarine swells, but to transform the gabbro mto its high-pressure facies, eclogite. The change of density from 3 to 3.3-3.5, and the simultaneous action of isostasy, would therefore lead to marked subsidence, and a deep would result. On this hypothesis we should expect to find deeps along belts where the ocean floor borders the compressed mountainous edges of the sial; precisely, in fact, where they do occur. Deeps, moreover, should not occur everywhere around such borders, for in many places a thin covering of sial over the original gabbro would effectively prevent their development.

Thus, the two kinds of material, sial and sima, adopted by Wegener to explain the two dominant levels of the earth's solid surface, continental and oceanic respectively, serve equally well to explain the upward and downward departures from those levels. Compression and over-thrusting of the sial increase its thickness without seriously altering its density. and so lead to the uplift of plateaux and mountain ranges. Compression of the sima along adjacent belts (if the sima be normally of gabbroid composition, and free from even a thin covering of sial) results in a marked increase of density, and so leads to the formation of the greatest tracts of subsidence—the occanic deeps.

If now we assume the following approximate data: Sial: mean density, 2.7 (ranging downwards in composition from granite to diorite, apart from its

superficial veneer of sediments);

Sima: mean density, 30, where composed of gabbroid material, and 34 where this is in the eclogite facies, or where the sima is composed of

we can balance a sial column through, say, Tibet, with an average altitude of 5 kin., against an eclogite column through an oceanic deep covered with, say, 8 km. of sea water If x be the depth of the level of equal pressure below sea-level, then approximately

 $2 \cdot 7(x-5) = 8-34(x-8)$ ; giving x = 467 km.

Applying this method to the average floor of the Pacific, we easily deduce a thickness of 25 km of gabbro underlain by 34 material (eclogite or peridotite); and finally, for the sial thickness corresponding to continental regions of average elevation we arrive at about 31 km., also underlain by 3.4 material In support of this figure the latest estimate made by Dr. Jeffrevs may be cited. His investigations of the records of the Jersey and Hereford earthquakes of 1926 indicated in each case a granite layer of about 10 km., underlain by an intermediate layer approximately twice as thick (M.N.R.A.S., Geophys. Suppl., I., 1927, p. 483). If I am right in interpreting the composition of the intermediate layer as quartzdiorite to diorite, then the sial of the neighbourhood of Great Britain, the North Sea, the English Channel, and the adjoining parts of Europe—a nearly average region, though slightly low-should be about 30 km.

Dr. Lawson and I have previously shown that radioactivity appeared to set a limit of 15 or 20 km. to the average thickness of the sial (Phil Mag, Dec. 1926, p. 1218). If, then, this thickness be really 30 km., it becomes certain that the radioactivity of the sial must fall off very rapidly in depth. Probably the most remarkable evidence supporting this hitherto , little explored possibility is to be found in the atomic weight and isotopic constitution of common lead. These show quite conclusively that no appreciable part of the latter has been derived from the disintegration of uranium and thorium during known terrestrial history. Otherwise the atomic weight of ordinary lead would range between 206.9 or less, and 207.2 or more. That there is a real distinction between ordinary lead and radioactively generated lead has now been finally demonstrated by Dr. Aston's recent success in obtaining the mass spectrum of lead (NATURE, Aug. 13, 1927). It follows from these results that, until the time of its dispersal through and concentration from magmas, the lead of common ores must have lain in an environment where it was not appreciably affected by admixture with generated lead. In other words, I suggest that the dioritic base of the sial through which ordinary lead may originally have been dispersed, is extremely poor in the radioactive elements uranium and thorium, relative both to the higher levels of the sial and to the underlying levels of the sima.

. Thus we see that an estimate of 30 km. (or a little over) for the mean thickness of the sial is in accordance with such widely different phenomena as the great depths of the oceanic deeps and the practical invariability of the atomic weight of ordinary ore-lead. Smaller estimates of thickness appear to leave ARTHUR HOLMES. both quite unexplained.

### The Golgi Apparatus in Higher Fungi.

THE Golgi material in plant tissues is only now being worked out Guilliermond of Paris in 1922 obes deligi apparatus in barley roots by the silver intation mon method; and in March 1926 he publicularly it aper in C R. Acad. Sci.. Paris, on the If the two itween the plant vacuolar system and the

Golgi apparatus. He treated the epidermal cells of very young leaves of Iris germanica and meristematic tissues of young shoots of Elodea canadensis. some Chlarophyceæ, Cyanophyceæ, bacteria, and some fungi (Levure and Oidium lactis), with the silver impregnation methods of Cajal and da Fano as well as with vital staining with neutral red. In the majority of cases he could obtain the precipitates of vacuoles (metachromatic corpuscles) stained in the form of the network of canals constituting the Golgi apparatus.

Botanists generally are of opinion that the plant vacuolar system and the Golgi canals of animal cells are morphologically and physiologically equivalent. This is further supported by the recent remarkable researches of Parat, who has shown that the Golgi apparatus in animal cells also consists of a number of vacuoles. By the silver nitrate method of Golgi I have obtained clear blackened networks in close association with the nuclei in cells of the root-tips of Allium, Lilium, and Canna.

It seems that the presence of Golgi bodies in higher fungi (especially Basidiomycetes) has not been reported as yet. For the last eight months I have worked on a number of our common Agarics and Polypores, col-

lected fresh and living, namely, Lentinus subnudus. Lepiota mastordeus, Flammula dilepis, Entoloma microcarpum, Psathyra lucipeta, Panaeolus cyanascens.

. 1 —Golgi apparatus in *Lentinus subnudus*; after fixing for 10 days in potassium bichromate and osmic acid. Camera lucida drawing, under immersion lens, Zeiss apochromat, 2 mm , N. A. 1.4  $\times$  1100

Schizophyllum commune, Polyporus zonalis, Ganoderma lucidum, Lenzites repanda, etc. The basidia of all of them were studied, and for the sake of close parallel comparison each specimen was simultaneously treated in four different ways, namely, (1) by fixing in Fleming's strong fluid mixed with an equal quantity of water, and finally staining the microtome sections (5-6  $\mu$  thick) with Heidenham's iron-hæmatoxylin, (2) by fixing in Bensley's fluid to study the form and the location of the vacuoles; (3) by fixing in Golgi's bichromate and silver nitrate method (rapid process): and (4) by vital staining with a very weak solution of neutral red.

By the silver impregnation method I could get within the basidia of the majority of specimens a clear network of blackened coil, usually corresponding with the position of the vacuoles. In some the black coil was found close to the top of the basidia, in some the coiled threads were at the bottom, and in others they were on the sides almost at the central part of the basidia. In Bensley's fluid the vacuolar system came out prominently as a unit. In Fleming's fluid the details of the nuclei were distinctly seen. Staining with neutral red, the metachromatic bodies within the vacuoles took a deep red stain in the form of droplets; big round drops taking a diffused stain showed in their interior a number of bodies deeply stamed; these vacuoles were found in varying posi-tions within the basidia. By successive trials it has been found that the specimens usually fixed in potassium bichromate and osmic acid from six to ten days shinton Hod formation of the Golgi apparatus. Some of the specimens showed the deposit of the fragments of black threads not yet united into a coil, these are what are known as 'Golgi bodies' as distinct from the 'Golgi apparatus.' Fig. 1 shows the Golgi apparatus in basidia of *Lentinus subnudus*.

I have camera-lucida drawings of a number of basidia from most of the specimens showing the presence of the Golgi apparatus. I hope to publish the details of each specimen in a later paper with the necessary illustrations.

# Sound Absorption Coefficients measured by Reverberation and Stationary-wave Methods.

There are two methods of measuring the amounts of sound absorbed by various materials. One is the reverberation method of W. C. Sabine, in which a specimen of the material to be tested is mounted on the walls of a reverberation chamber and the coefficient of absorption is deduced from the effect which the presence of the specimen has on the rate of decay of sound in the chamber. The other consists in placing the specimen at the end of a pipe down which sound-waves are made to pass. The reflected and incident waves interfere, and the coefficient of absorption is calculated from observations made on the interference pattern within the pipe.

The advantage of the second method is that only

The advantage of the second method is that only small specimens are needed for a test. Generally a specimen with an area of not more than I square foot is sufficient, whereas for a reverberation test an area of about 100 square feet is needed. It is obvious, however, that the coefficients measured by the two methods will not necessarily have the same value. In the pipe (or 'stationary-wave') method it is the coefficient of absorption at normal incidence which is measured, whereas in a reverberation test (according to current theory) sound impinges on the specimen at all angles of incidence from 0° to 90°

all angles of incidence from  $0^\circ$  to  $90^\circ$ . In a recent paper (*Proc. Roy. Soc.*, A, vol. 115. pp. 407-419, 1927) I have shown how the coefficient of absorption of an 'acoustic plaster' can be calculated for any angle of incidence from the 'acoustical admittance', a quantity which can readily be determined from observations made with stationary-wave apparatus. If  $\Omega_1 + \Omega_2$  is the acoustical admittance per unit area of the absorbing material, and  $\alpha$  is the velocity of sound in air, it is shown that the coefficient of absorption for sound incident at angle  $\theta$  is given by

$$a_{\theta} = 1 - \frac{(\cos\theta - a\Omega_1)^2 + (a\Omega_2)^2}{(\cos\theta + a\Omega_1)^2 + (a\Omega_2)^2}.$$

This expression can be introduced into the theory of reverberation as usually developed (for example by E. Buckingham, Sci. Papers of the Bureau of Standards, No. 506. p. 201), and the 'reverberation' coefficient of absorption, say ... can then be found in terms of acoustical admittance. In this way I find that the reverberation coefficient is given by

$$\begin{split} a &= 8a\Omega_1 \bigg[ \, 1 - a\Omega_1 \log_s \frac{a^2(\Omega_1^{\,\, 2} + \Omega_2^{\,\, 2}) + 2a\Omega_1 + 1}{a^2(\Omega_1^{\,\, 2} + \Omega_2^{\,\, 2})} \\ &\quad + \frac{a^2(\Omega_1^{\,\, 2} + \Omega_2^{\,\, 2})}{a\Omega_1} \, \bigg\{ \tan^{-1} \left( \frac{1 - a\Omega_1}{a\Omega_2} \right) - \tan^{-1} \left( \frac{a\Omega_1}{a\Omega_2} \right) \bigg\} \, \bigg]. \end{split}$$

vol. 115, pp 417-418, 1927). From this we find that the coefficient at normal incidence is  $a_0=0.28$ . This is the coefficient as usually measured by the stationary wave method. From the expression just given it is found that the reverberation coefficient is a=0.45. Hence the reverberation coefficient of the acoustic plaster is much greater than the coefficient at normal incidence. Some support is given to this result by the values of the coefficients for the acoustic tile known as 'Akoustolith.' Stationary-wave measurements at 512 vibrations per second give 0.26 for the absorption at normal incidence (*Proc. Phys. Soc*, vol. 39, p. 281, 1927), while the reverberation absorption coefficient is reputed to be between 0.36 and 0.38. F. R. Watson ("Acoustics of Buildings," p. 25) quotes 0.36. The difference is not so marked as that calculated for the modified Sabine plaster, but it is in the same sense.

The practical importance of establishing a relation between absorption coefficients by the reverberation method and those found with stationary-wave or similar small-scale testing apparatus is obvious, although it appears to have been sometimes overlooked or ignored in the past.

#### Flame and Combustion.

If I know not the meaning of the voice, I shall be unto him that speaketh a barbarian and he that speaketh a barbarian unto me.

In my early days, I happened to be present in Vice-Chancellor Bacon's court when a ward in Chancery came up to be spoken with. After a long whispered conversation with her the Vice-Chancellor said to her counsel: "Mr ---, the lady does not know her mind; when she knows her mind, let her again come here and speak with me." The young lady protested indignantly 'that she did know her mind '—but to no purpose. After a few more words with her, the judge repeated what he had said Counsel took the hint and bore the fair protesting one away. Messrs. Bone, Townend and Co (NATURE, Nov. 12, p. 694) are like that lady: they have burst violently into flame without having mastered the very tangled story of the great drama of chemical interchange which 'flame' connotes. Like the modern school boy and college-student, they want teacher to learn them their lessons. I have always been against spoon feeding. Moreover, Prof. Bone is the last person to learn through others. When the firm has full grip of the case, if here, I shall be pleased to speak with them. Thus far but no further does my imagination go at present It is not for me even to help on a decision whether it be safe to accept its guidance at any time.

Prof. Finch seems to have made interesting experiments. He always does and I have the very highest regard for his work. To dissect out the meaning of his observations will not be easy and is not even to be attempted upon such premature partial publication. Still, I may say, that I fail to understand how even that marvellous material 'water' can play an electrical and not a chemical part. I must confess that I am old-fashioned enough—if not medieval—to retain my faith in one Faraday and that I regard the two 'parts' as inseparable and interdependent, perhaps also because I learnt physics and chemistry as one subject in my blameful youth. Here is necessary to think down to the intimate interchange. This no one will do.

Mr. Egerton, too, appears to have made

observations but he also uses language so ambiguous that it is scarcely possible to guess what he means Thus, he concludes that the process of combustion is "autocatalytic." This sounds very learned. The statement must carry profound conviction and endless joy to the 'anti-knock' soul. Yet, what does it mean, how will it help us to make the internal com-bustion engine efficient 'Catalytic' is one of those blessed words which carry no particular meaningthe shibboleth of the day, lisped in every scientific nursery. At least three special perambulators have been chartered to carry the infant catalysis 'hopping' in chemists' gardens. Yet neither the Cambridge nor the Princeton nor the Johns Hopkins nuise can tell us what mission the baby is bawling. I see the note dates from Oxford Looking this up in my Gazetteer, I find: A place where grass grows and dictionaries are made, but the meanings of words are not calculated in use. Then, in the new volume of the "Dictionary of National Biography," I find the statement made of the late Loid Rayleigh: "There still lingers in Cambridge a tradition as to the lucidity and literary finish of his answers in this examination [the Mathematical Tripos]. Every paper he wrote, even on the most abstruse subject, is a model of clearness and simplicity of diction" When we can say this of the papers we write on combustion, perhaps we shall begin at least to know where we are not.

HENRY E. ARMSTRONG.

### Movements of the Lower Jaw of Cattle during Mastication.

Among the biological phenomena exhibiting a definite sense of rotation, as, for example, the growth of certain creepers and of the shells of snails, one that does not seem to have been studied and to which we wish to direct attention here, is the masticating motion Close investigation shows that the lower jaw of the animal is displaced with respect to the upper jaw, not in a purely horizontal or a purely vertical direction, but simultaneously in both directions with such a phase difference that a clearly evident rotation results. Theoretically this can, of course, take place in two senses, and observation teaches that both possibilities are realised in Nature. Taking the direction of the food as positive, we shall denote as right- and left-circular cows those of which the chewing motion, viewed from the front, turns clockwise and counterclockwise respectively.

This nomenclature is based on the tacit assumption that one and the same cow always maintains its sense of rotation. We could confirm this by a limited number of observations but are aware that more complete data, extending over longer periods of time, are necessary definitely to settle this point. Statistical investigations on cows distributed over the northern part of Sjælland, Denmark, led to the result that about fifty-five per cent. were right-circular, the rest leftcircular animals. As one sees, the ratio of the two kinds is approximately unity. The number of observations was, however, scarcely sufficient to make sure if the deviation from unity is real. Naturally these determinations allow no generalisation with regard to cows of different nationality.

The fact that both senses of rotation are realised raises the question if simple laws govern the hereditary transmission of the property referred to. Concerning the snails mentioned above, one knows that Mendel's laws in their simplest form apply, while in most other cases the actual occurrence of only one sense of intation makes such investigations impossible. Parheularly it would be interesting to ascertain which of the two modifications is the dominating one. We are, unfortunately, not in a position to bring evidence on this important point, but believe that those having a more intimate acquaintance with cattle will find it easy to give an answer. P. JORDAN.

#### Polarisation Effects in Measuring Electrostatic Fields.

In listening to a lecture by Dr. Aston, in which the mass spectrograph was described, the writer was interested to hear that a polarisation of the plates of the condenser determining the electrostatic deflexion of the positive rays affected the field to such an extent to be one of the causes which made it necessary to necur to relative measurements in interpreting the results. Dr Aston mentioned that the effect could be reduced by gilding the plates.

A few years ago attention had been centred on these polarisation or double layer effects in connexion with X-rays, in discussing the question how far such a layer formed under the influence of the electronic bombardment of the anticathode might affect the velocity of the electrons reaching the target. It is remarkable that they are so prominent in positive ray experiments, where the cathodic bombardment cannot be intense.

In Dr. Aston's determinations the polarisation was a disturbance, which he was able to trace in his results

and to eliminate entirely.

Few physicists are in this fortunate position and to the writer it seems of interest to direct attention to the fact that, so long as no greater knowledge as to the conditions determining the magnitude of these polarisation effects is obtained, they constitute a particular source of error, which is but too easily overlooked in a number of cases where the production of stray rays cannot be eliminated, for example, in the determination of em for the electron according to some classical methods. J. Brentano.

The University. Manchester, Nov 12.

### Biology and Birth-Control.

It would interest me, and possibly some of your readers, if the writer of the review of my "Right of the Unborn Child" in NATURE of Nov 5 would cite the sentences in which, according to him, I make "contemptuous remarks about God." KARL PEARSON.

University College, London, W.C.1.

THE answer to Prof. Pearson's question is that he quoted with approval. as expressive of his meaning, J. C. Squire's lines, including "Good God! said God. 'I've got my task cut out'" This seems to me contemptuous, and even blasphemous. E. W. MACBRIDE.

### The 'Green Flash.'

REFERRING to page 728 of NATURE of Nov. 19, greenish appearances at sunset and sunrise may be due to various causes: but I am personally convinced that the sudden green flash, seen by some people when the last rim of the sun disappears behind a sharp horizon, is mainly physiological; for I see (if it can be called seeing) a momentary greenness when I switch off a bright lamp, with metallic filament, suspended above my bed. OLIVER LODGE.

Normanton House, Lake, Salisbury.

### Alloys and their Importance in Engineering.

IN an interesting and suggestive presidential address delivered to the Institution of Mechanical Engineers on Oct 21, Sir Henry Fowler paid a tribute to the help that mechanical engineering has received, in the solution of many of its most difficult problems, from the work of the man of science. Particularly he attributed the remarkable changes that have taken place since Stephenson built the Rocket to new materials and the physical states in which they can be supplied, and in large measure these have been the outcome of scientific The whole profession of mechanical engineering is to-day dependent on metals. "Although many ingenious contrivances have been made from wood and stone, mechanical engineering only commenced when metals became available for use."

In the middle of the nineteenth century, railways were developing very rapidly and the makers of iron rails could not cope with the demand, but the truly scientific work of Bessemer and his production of steel relieved the situation. Between 1850 and 1926 the world's production of cast iron grew from  $4\frac{1}{2}$  million tons to 77 million tons. In 1870 the total steel produced was less than  $\frac{1}{2}$  million tons; in 1927 more than 90 million tons were made. Only three metals were used for the manufacture of the Rocket; to-day, on the L.M.S. railway, fifty-five specifications for metals are used, and the British Engineering Standards Association has prepared standard specifications for more than 100 varieties of steel. Sir Henry Fowler pointed out that the work of Bessemer and of Siemens and Martin insured for many years a sufficient quantity of steel, but the work of two other men of science, Thomas and Gilchrist, who in 1876 discovered that phosphorus could be very appreciably diminished by using a basic lining in the melting furnace, increased enormously the possible supplies.

The improvement and control of the quality of steels by improved methods of manufacture and the development of new alloy steels for tools and other purposes have revolutionised not only the methods of the machine and fitting shops, but also the designs of all types of machines and structures. The development of photomicrography and the pyrometer have contributed in no small measure to the success that has been achieved. Michael Faraday a century ago in England, and Berthier in France, experimented on alloys of nickel and chromium, but it was not until 1857 that Mushet alloyed tungsten with iron and made self-hardening steel: the remarkable developments in cutting speeds and in automatic machinery, consequent upon the new alloy tool steels, has almost entirely taken place, however, during the last twenty-five In 1882, Hadfield produced the manganese steel, so largely used to-day, because of its hardness, for points and crossings and dredger buckets, and later produced the silicon steel which has had very remarkable effects upon the construction of transformers and other magnetic and electrical apparatus.

During the twentieth century the nickel and nickelchromium steels and the so-called molybdenum and vanadium steels made by the addition of small quantities of these metals to the nickel-chromium steels have not only played a considerable part in the development of the automobile and the aeroplane, but steels have also been produced having remarkable magnetic, or non-magnetic, properties and others which resist both corrosion and high stresses at normal and high temperatures in a remarkable manner. Some of these alloys resist the action of the strongest acids and are proving of the greatest service in the chemical industry. Others are not only valuable for case-hardening boxes and heating pots but also give promise of helping in the solution of difficulties in superheater elements, in the development of high temperature - high pressure vessels for distillation and synthetic processes and the gas turbine.

Turning from steels to the non-ferrous metals, the developments in the copper alloys, bronzes and brasses, and in the aluminium alloys, have been equally remarkable. Muntz metal was the first of the alloys of copper that could be forged and extruded, but it was not until mass production became important that full advantage of this alloy was taken. To-day the British Engineering Standards Association specifications demand for high tensile brass a breaking strength of 45 tons per sq. inch, and for brass bars 28 tons per sq. inch, and an elongation per cent. of 25 per cent. on a gauge length of not less than four diameters.

Alloys of copper—brasses and bronzes—of greater strength than these are possible. In these developments the work of contributors to the reports of Alloys Committee of the Institution of Mechanical Engineers has played an important part.

Aluminium in the commercial form has only been known for thirty-five years. In 1913 the world's production of aluminium was 64,000 tons, but in 1926 this had risen to 235,000 tons. In the pure state it is of comparatively little use to the engineer, but when alloyed with zinc and copper. with copper, manganese, and magnesium (4 per cent. Cu, ½ per cent. Mn, ½ per cent Mg as duralumin), with copper, nickel, and magnesium (4 per cent. Cu, 2 per cent. Ni,  $1\frac{1}{2}$  per cent. Mg as Y alloy), with copper and silicon (a 4 per cent. Cu, 4 per cent. silicon is a good casting alloy for sund or die), and with other metals, a remarkable series of light alloys having specific gravities from 2.8 to 3.1 have been produced alumin can be forged, extruded, and cold drawn, and by suitable heat treatment can be made to give a breaking stress of 32 tons per sq. inch with from 6 to 10 per cent. elongation Y alloy can be hot rolled and heat treated to give 24 tons per sq. inch and 23 per cent. elongation; all the other alloys can be cast into intricate shapes, and some of them make admirable die castings. For many parts of aeroplanes, aeroplane engines,

and automobiles these alloys have proved invaluable. In the I7 ited States of America railway carriage frames? e being constructed of duralumin. thus diminishing the dead weight, as compared with the net weight carried, very considerably Die castings of intricate shapes, such as gear wheels. are now being made, to a remarkable degree of accuracy, of aluminium bronzes-alloys of copper and aluminium, containing more than 80 per cent.

The rapidity with which these alloys have been developed and have won the confidence of engineers is a tribute to the careful scientific work that has been done in connexion with their constitution and physical properties The success achieved by the aluminium alloys has encouraged a number of workers to investigate the possibilities of alloying magnesium, which has only a specific gravity of 1 7 as compared with 2.67 for aluminium, with other metals, and already some success has been achieved in the application of magnesium allovs, containing more than 90 per cent of magnesium, to the manu- he that hath little business shall become wise."

facture of high-speed pistons for internal combustion engines and other purposes

Sir Henry Fowler paid a tribute to the important research work done in the great works, at the National Physical Laboratory and also at the universities, but he emphasised the necessity for researches conducted jointly by men of science and engineers. Unfortunately, he did not suggest any method whereby the ability at present in the universities, which owing to pressure of teaching and other routine duties is not able, except at the cost of health, to apply itself to the solution of many problems with which industry is faced, can be given the necessary time and means to carry out research The only hope seems a more generous provision of funds for the direct assistance of research in the engineering and metallurgical departments of the universities, in order that the condition of the apt quotation with which the address 'The wisdom of the concluded may be fulfilled scribe cometh by the opportunity of leisure and

## Scientific Aspects of Intense Magnetic Fields and High Voltages.<sup>1</sup>

By Sir Ernest Rutherford, O.M., Pres.R.S.

TN the past our laboratories have had to be content with the comparatively weak magnetic fields provided by the ordinary electro-magnets and the voltages supplied by simple electrostatic machines and induction coils. In order to push further our investigations in many directions, much stronger magnetic fields and higher voltages are required in the laboratory Scientific men thus naturally follow with great interest advances in these directions, whether undertaken for purely scientific or for technical uses.

By means of modern electrostatic machines it is not difficult to produce weak direct currents at. potentials from 200,000 to 300,000 volts, while a large well-insulated induction coil can give momentary voltages of a similar magnitude. The wide use of X-rays for diagnostic and therapeutic purposes has led to a marked improvement in apparatus for exciting intense X-rays. The requirement of very penetrating X-rays for deep therapy in our hospitals has led to the construction of comparatively light transformers, which will supply the requisite small currents at voltages between 300.000 and 500,000

One of the simplest ways of producing very high voltages is by the Tesla transformer, in which the oscillatory discharge of a Leyden jar is passed through the primary of an air transformer. In this way it is not difficult to produce voltages in the secondary of the order of a million volts, and I understand as much as five million volts have been obtained in the Carnegie Institution of Washington The striking effects produced by these rapidly oscillating discharges from a Tesla coil, and the immunity with which long sparks may be taken through the body, are well known to all. rapid frequency of the oscillations and the compara-

 $^{\rm 1}$  From the presidential address delivered at the anniversary meeting of the Royal Society on Nov. 30.

tively small energy given to the secondary of a Tesla coil has, however, restricted its use for general technical purposes as a source of high voltages, although it is now finding an application for the testing of insulating materials.

In order to transmit electrical power economically over long distances, there is a continuous tendency to raise the voltage in the transmission This increase of the operating voltage has led to the need of very high voltages to test the insulating properties of these lines and their transformers and the effect of electric surges in them In the course of the last few years a number of high-voltage plants have been installed for testing purposes in various countries, which give from one to two million volts. These voltages may be obtained either by a very large well-insulated power transformer or more generally by a cascade method employing several transformers in which the secondary current of one transformer passes through the primary of a second, and so on, the cores of the successive transformers being mounted on insulating pedestals. This cascade method is very advantageous for the purpose, since it allows a great reduction in weight and dimensions of the transformers. Such a high-tension plant in full operation is a striking sight, giving a torrent of sparks several yards in length and resembling a rapid succession of lightning flashes on a small scale. Actually the highest voltage so far obtained by these methods is very small compared with the voltage in a normal lightning flash from a cloud to the earth, where the difference of potential may be as high as a thousand million volts.

There appears to be no obvious limit to the voltages obtainable by the cascade arrangement of transformers, except that of expense and the size of the building required to install them. I am informed that the General Electric Company of Schenectady has a working plant giving 2,800,000 volts (max ), and hopes soon to have ready a plant

to give 6 million volts

While no doubt the development of such high voltages serves a useful technical purpose, from the purely scientific point of view interest is mainly centred on the application of these high potentials to vacuum tubes in order to obtain a copious supply of high-speed electrons and high-speed atoms. So far, we have not yet succeeded in approaching. much less surpassing, the success of the radioactive elements, in providing us with high-speed  $\alpha$ -particles and swift electrons. The  $\alpha$ -particle from radium Cis liberated with an energy of 7.6 million electron volts, that is, it has the energy acquired by an electron in a vacuum which has fallen through this difference of potential. The swiftest  $\beta$ -rays from radium have an energy of about 3 million electron volts, while a voltage of more than 2 million would be required to produce X-rays of the penetrating power of the y-rays

The application of high voltages to vacuum tubes presents serious technical problems, but a vigorous attack on this side of the question has been recently undertaken by Dr. Coolidge. In 1894, Lenard made the discovery that high-speed cathode rays generated in a discharge tube could be transmitted into the open air through a very thin window, and made very important observations on the laws of absorption of these swift particles The voltage used to accelerate the electrons in these experiments seldom exceeded 80,000 volts and the ravs were stopped in passing through a few inches of air. Taking advantage of the great improvements in vacuum technique and the ease of supply of electrons from a glowing filament, Dr Coolidge has constructed an electron tube which will stand 300,000 volts, the rays passing into the air through a thin plate of chrome-nickel-iron alloy about

0.0005 inch thick.

It has not so far been found practicable to apply much more than 300,000 volts to a single tube, on account of the danger of a flash over, due possibly to the pulling-out of electrons from the cathode by the intense electric field. For the application of still higher voltages, a number of tubes are arranged in series and communicating with one another, the fall of potential in each being about 300,000 volts. In these preliminary experiments, a large induction coil has been used to generate the voltage. So far, experiments have been made with three tubes in series and 900,000 volts, giving a supply of electrons corresponding to one or two milliamperes through the thin window in the last tube. This gives an intense beam of high-velocity electrons, which spreads out into a hemisphere, due to the scattering of the electrons in passing through the metal window and the surrounding air, extending to a distance of about two metres from the window. Marked luminous effects are produced in the air itself and in phosphorescent bodies placed in the path of the rays. I am informed by Dr. Coolidge that further experiments are in progress, and it is hoped to extend the system for still higher voltages.

While the energy acquired by the individual electrons in falling through 900,000 volts is smaller than that possessed by the swifter  $\beta$ -particles expelled from radium, the number emitted from the electron tube is very much greater; for example, the number of electrons per second corresponding to a current of 2 milliamperes is equivalent to the number of  $\beta$ -rays emitted per second from about 150,000 gm. of radium in equilibrium.

While important progress has been made in artificially producing streams of swift electrons, there is still much work to be done before we can hope to produce streams of atoms and electrons of a much higher individual energy than the aor  $\beta$ -particle spontaneously liberated from radio-As we have seen, the  $\alpha$ -particle from radium C is initially expelled with an energy of about 8 million electron volts So far, the a-particle has the greatest individual energy of any particle known to science, and for this reason it has been invaluable in exploring the inner structure of the atom and giving us important data on the magnitude of the deflecting field in the neighbourhood of atomic nuclei and of the dimensions of the nuclei In case of some of the lighter atoms, the a-particle has sufficient energy to penetrate deeply into the nucleus and to cause its disintegration, manifested by the liberation of swift protons.

It would be of great scientific interest if it were possible in laboratory experiments to have a supply of electrons and atoms of matter in general, of which the individual energy of motion is greater even than that of the a-particle. This would open up an extraordinarily interesting field of investigation which could not fail to give us information of great value, not only on the constitution and stability of atomic nuclei but also in many other

directions

It has long been my ambition to have available for study a copious supply of atoms and electrons which have an individual energy far transcending that of the a- and  $\beta$ -particles from radioactive bodies. I am hopeful that I may yet have my wish fulfilled, but it is obvious that many experimental difficulties will have to be surmounted before this can be realised, even on a laboratory scale.

We shall now consider briefly the present situation with regard to the production of intense magnetic fields. Electro-magnets are ordinarily employed for this purpose, and the magnetic fields obtainable are in the main limited by the magnetic saturation of the iron. By the use of large electromagnets and conical pole pieces, the magnetic induction can be concentrated to some extent. For example, in the large Weiss electro-magnet, a field of 80,000 gauss can be obtained over a volume corresponding to about a pm's head, and a field of about 50,000 gauss through a volume of about 20 cubic mm In general, however, most experiments have been restricted to fields less than 35.000 gauss.

In order to push this method of obtaining

magnetic fields to the practical limit, Prof Cotton, of Paris, has designed and has under construction a very large electro-magnet The cross-section of the iron will be of the order of one square metre, and about 500 kilowatts will be required to excite it. Such a large electro-magnet will not give a much stronger maximum field than existing ones, but will produce a field of given intensity through a larger volume No doubt this electro-magnet will prove very useful in experiments where steady fields of high intensity are required through a reasonable volume.

In order to provide magnetic fields of the order of half a million gauss, the use of the electro-magnet must be abandoned Some years ago, Dr Kapitza suggested that intense momentary magnetic fields could be obtained by sending a very strong current through a coil for such a short interval that the heating effect in the coil is restricted to a permissible value It is well known that momentary currents of great intensity can be produced by the discharge of a large high-voltage condenser through Experiments of this kind have been made by Dr Wall, in which the duration of the discharge was of the order of one-thousandth of a second. It is estimated that in this way a field of about 200,000 gauss may be reached.

In his experiments to obtain intense magnetic fields, Dr. Kapitza at first employed a special form of accumulator to send a very strong current through a coil for about one-hundredth of a second, the current if necessary being sharply broken after this interval. In this way it was shown to be practicable to carry out experiments on the Zeeman effect, and in bending  $\alpha$ -particles in magnetic fields considerably stronger than those obtainable with ordinary methods. In subsequent experiments, a generator of special design was installed, which gives a very large current, of the order of 70,000 amp, at 2000 volts when short-circuited. A heavy current from the generator is passed for about one-hundredth of a second through a coil and then sharply broken by means of a specially designed automatic break By this means very strong momentary currents can be produced

The main difficulty in these experiments has been to construct a coil strong enough to withstand the enormous disrupting forces which arise when a large current is passed through the coil. By special attention to the design, a coil has been made which gives

a field of 320,000 gauss over a volume of about 3 c c. without any signs of fracture Measurements have been regularly carried out in fields of this magnitude. It is anticipated that the present design of coil will give about 500,000 gauss before bursting, and that still higher fields can be obtained in coils specially constructed for the purpose.

As the current only lasts about one-hundredth of a second, oscillograph methods have to be employed to determine the strength of the current and magnetic field 
There seems to be no inherent difficulty in conducting magnetic experiments in these momentary fields, for the shortness of the time available is in many cases compensated for by the magnitude of the effects which arise in such intense fields. The investigations, which have been carried out in the Cavendish Laboratory, have been made possible by the generous support of the Department of Scientific and Industrial Research, which has defrayed the cost of the apparatus and experiments

The application of these new methods of producing intense fields opens up a wide region of research, where all magnetic properties can be examined in fields ten to twenty times stronger than those hitherto available. Such researches cannot fail to yield results of great interest and importance and to advance our knowledge of

magnetic phenomena.

While the application of external magnetic fields of the order of one-million gauss will no doubt markedly perturb the orbits of electrons in the outer structure of the atom, it is not to be anticipated that they will seriously affect the stability of atomic nuclei. General evidence indicates that the magnetic fields within the nucleus are much too great for such a relatively weak external field to cause a disruption of the nucleus. In this direction, the bombardment by high-speed particles is likely to be far more effective than the strongest magnetic field we can hope to generate.

This advance of science depends to a large extent on the development of new technical methods and their application to scientific problems. The recent work to which I have referred, on the development of methods of producing high voltages and intense magnetic fields, is not only of great interest to scientific men in itself but also promises to provide us with more powerful methods of attack on a

number of fundamental problems.

#### News and Views.

In February 1925 the residuary trust funds of the estate of the late Dr. Conway Evans, medical officer for the Strand district, who died in 1892, were transferred to the president of the Royal Society and the president of the Royal College of Physicians of London, and their successors in office, that in accordance with the terms of his bequest they "shall apply the same in giving rewards to such person or persons who, in the opinion of the Presidents, have rendered, or shall from time to time render, some valuable contribution or addition to science as it exists at the time of my death, either by invention, discovery, or otherwise" In accordance with this trust, the president of the Royal Society and the president of the Royal College of Physicians of London have made the first award of the Conway Evans Prize, amounting to 500 guineas, to Sir Charles Sherrington, on the ground that his work on the physiology of the nervous system, and chiefly on the physiology of the brain and spinal cord of the higher animals, has brought many complex nervous functions for the first time within the range of investigation and analysis. His discoveries have had a profound influence throughout the world on the experimental sciences of physiology and psychology and have thrown a flood of new light on many of the symptoms of nervous disease. In making this first award for some valuable contribution to science as it existed at the time of the death of the testator, the presidents of the Royal Society and of the Royal College of Physicians state that they have had no hesitation in selecting as conspicuously worthy of such recognition the work of Sir Charles Sherrington, which they believe to be of outstanding value for science and for humanity.

The twenty-fifth annual report of the Imperial Cancer Research Fund gives an account of another year of steady progress without any sensational discoveries. The interesting facts about multiple tumours receive special attention. Two independent cancers in the same person are very uncommon, and it has been found impossible to produce tar-cancer in mice after removal of a spontaneous mammary cancer or of an experimental cancer One malignant tumour evidently causes the body to do something which to some extent protects it against another tumour. The nature of this mechanism is under investigation: it nught well be the explanation of some of the vagaries of the occurrence of cancer in man. As in most cancer research institutes, the hypothesis of Gye and Barnard is under intensive examination. confirmatory results have been obtained, but there is as yet no unanimity about the facts or their interpretation. The financial position of the Fund is fairly satisfactory, but an uncomfortably large proportion of the income comes from temporary and casual sources.

WE learn from the Annual Report of the British Photographic Research Association that the Department of Scientific and Industrial Research has offered to the Association a block grant for the five years ending May 31, 1932, that will make up the income of the Association from other sources (its members' subscriptions) to £5000 per annum. There are certain conditions, and the one that is essentially new requires the appointment of a "Research Committee of technical and scientific persons in whom shall be vested the supervision of the scientific investigations of the Association." It is very satisfactory to know that, although the income of the Association will probably be rather less than it has been, the useful work that it has been carrying on for the last ten years will be continued. The Report gives the details of the last year's work, and states that investigations into the fundamental properties of the silver halides are being continued in order to ascertain whether the mechanism of the latent image formation can be connected directly with some purely physical property which can be studied in the absence of such complicating factors as gelatin.

The kinematograph film is being increasingly used for educational purposes, and we note with interest that two films dealing with disease-carrying insects have recently been produced by the National Department of Health of Argentina, one on the house-fly and its relation to disease, and the other on mosquitoes and malaria. Both films were prepared at Buenos Aires under the direction of Dr. Barbará, of the

Bacteriological Institute, but though primarily intended for propaganda purposes in Latin America, they could readily be adapted for instructional courses in medical entomology elsewhere; we believe copies can be obtained on loan. The house-fly film is particularly good, and includes photographic records from Nature of the complete life-history of the fly; habits of adults, oviposition (the actual deposition of an egg is shown), egg-hatching, larval growth and movements, pupation and hatching of adults The characteristics of various Muscidæ are shown, and there are some remarkable photographs of the development of bacteria and the life-history of trypanosomes. mosquito film is not quite so full, and the producers have made greater use of drawings and diagrams, but the life-history of culicine mosquitoes is well shown, also various control methods, and the development of malarial parasites, besides symptoms and treatment of the disease

THE following appointments have been made by the principal trustees of the British Museum · Mr. R. A. Smith, to be Keeper of British and Medieval Antiquities, in succession to Mr O. M. Dalton, who retires in December, Mr. E. J. Forsdyke, to be a Deputy Keeper in the Departments of Antiquities, in succession to Mr. R. A. Smith; Mr. H I. Bell. to be a Deputy Keeper in the Department of Manuscripts, in succession to Mr. J. A. Herbert, who has just retired. The principal trustees have also made the following appointments in the Natural History Museum: Dr. L. J. Spencer, to be Keeper of Mineralogy, in succession to Dr G. T. Prior, who retires on Dec. 16; Dr. W. D. Lang, to be Keeper of Geology, in succession to Dr F. A. Bather, who retires next February. Mr. J. Ramsbottom, to be a Deputy Keeper in the Department of Botany, on the promotion of Dr. Spencer; Mr. M. A. C. Hinton, to be a Deputy Keeper in the Department of Zoology, on the promotion of Dr. Lang.

In February next, after forty years' service in the British Museum (Natural History), Dr F. A. Bather retires from the post of Keeper of the Department of Geology. His vigorous and cheery personality will be missed by geologists visiting the Museum no less than by his colleagues. Educated at Winchester and Oxford, he joined the staff of the British Museum in 1887 as assistant in the Department of Geology, and was placed in charge of the Echinoderma. After becoming assistant keeper, and later deputy keeper, he succeeded Sir Arthur Smith Woodward as Keeper of the Department in 1924 Dr Bather was elected F.R.S. m 1909; was awarded the Lyell Medal by the Geological Society in 1911; has been president of Section C of the British Association, and of the Museums Association; he is now president of the Geological Society. Dr. Bather's original work on the palæontology of the echinoderms has gained him a world-wide reputation, and amongst the distinguished palæontologists of to-day he stands in the front rank. His memoirs and papers are too well known to need mention here; not only are they models of scientific method, but also they possess a literary charm seldom found in the writings of scientific authors.

In his presidential addresses to Section C of the British Association at Cardiff (1920), and to the i in the British Museum (Natural History), who retires Geological Society last February, Dr. Bather dealt in a masterly manner with the principles of palæontology, and his listeners felt that those addresses were worthy of Huxley. Dr. Bather does more than look on fossils from the point of view of a morphologist and evolutionist; as is so well shown in his "Caradocian Cystidea of Girvan," he regards them as animals which once lived, and endeavours to correlate form with function, morphology with physiology. For several years Dr. Bather contributed the section on Echinoderma to the Zoological Record; although these are masterpieces of bibliography and analysis, one cannot avoid a feeling of regret that so much of his time was taken away from original research. In another direction, by the active interest which he has taken in the work of the Museums Association. Dr. Bather has rendered good service to his country; he has contributed many papers to the Association's journal dealing with the preparation and exhibition of specimens and other matters of importance to the curators of provincial museums. After his release from the cares and responsibilities of office, all who know Dr. Bather, whether personally or only from his writings, will fervently hope that leisure and health will enable him to continue for many years his splendid work in palæontology.

Dr. W. D. Lang, who has been appointed Keeper of the Department of Geology in the British Museum in succession to Dr. F. A. Bather, was educated at Harrow and at Pembroke College, Cambridge. He graduated in 1901, and obtained the degree of Sc.D. in 1919. Dr. Lang became an assistant in the Department of Geology in 1902, and was placed in charge of the lower groups of mvertebrates; he became assistant-keeper in 1924, and afterwards deputykeeper in the Department. His palæontological work deals mainly with corals and Polyzoa, treated from an evolutionary viewpoint-his conclusions concerning genetic relationship being based on ontogeny and zonal succession as well as on morphological characters. Of his numerous memoirs on these groups of fossils, we can only mention "Growth-stages in Parasmilia" (1909), "The Pelmatoporinæ, an essay in the evolution of a group of Cretaceous Polyzoa" (1919), and "Catalogue of the Fossil Bryozoa (Polyzoa) in the British Museum: Cretaceous" (1921, 1922). In a series of papers in the Proceedings of the Geologists' Association, Dr. Lang has done yeoman service for students by his lucid exposition of some of the general principles of palæontology; of these papers we may name "Old Age and Extinction in Fossils," "Homeomorphy in Fossil Corals," "Trends in Carboniferous Corals." Dr. Lang has not confined himself to work in the Museum, but for many years has devoted his vacations to the investigation of the faunal succession of the Lias of the Dorset coast; the last of his numerous papers on this subject was read before the Geological Society on Nov. 16. We feel confident that Dr. Lang will worthily maintain the high standard set by his two predecessors in the Department of Geology.

on Dec. 16 at the age of sixty-five years, entered the museum in 1887 to fill the vacancy caused by the death of Walter Flight, who had done the greater part of the chemical work of the department Dr. Prior was well qualified for this work. He had obtained a demyship in natural science at Magdalen College, Oxford, in 1881, and gained a first class in the honours schools of natural science in both chemistry (1885) and physics (1886), and had also studied for a short time in Germany. His papers on chemical mineralogy dealt with many minerals presenting interesting problems for the analyst, such as the niobates and tantalates of the rare earths, the cerargyrite group, and some of the sulpharsenites and sulphantimonites of copper and silver. About 1893 he undertook the care of the rock collections in the department in addition to his chemical work, since when he has published many petrographical papers of which the most important are his account of the volcanic rocks of British East Africa and the report on the rock specimens collected by Scott's (Discovery) Antarctic Expedition of 1901-4 On the appointment of Sir Lazarus Fletcher as Director of the Natural History Museum in 1909, Dr. Prior was made Keeper of Minerals. He then turned his attention to the meteorite collection, and here he found ample scope for careful critical chemical investigation, which led to the publication of numerous descriptions of meteorites and two papers of particular interest giving his views on their genetic relationships and classification. In addition he has written a "Catalogue of Meteorites," giving a full account of the falls represented in the museum collection. He was elected a fellow of the Royal Society in 1912, and was awarded the Murchison Medal of the Geological Society in 1927. He is now president of the Mineralogical Society, of which he had been the secretary since 1909.

DR. GEORGE THURLAND PRIOR, Keeper of Minerals

Dr. Leonard James Spencer, who succeeds Dr. G. T. Prior, entered the Department of Minerals in 1894. He was then twenty-four years of age, and had studied at Bradford Technical College, at the Royal College of Science in Dublin, and at Cambridge, where he was a scholar of Sidney Sussex College. He gained a first class in Part 2 of the Natural Sciences Tripos in 1893, taking geology, for which he was awarded the Harkness Scholarship. Before taking up his duties at the museum he studied for a short time under Prof. Groth in Munich. He has published a great number of papers on descriptive mineralogy, including accounts of the new minerals miersite, parahopeite, tarbuttite, chloroxiphite, and diaboleite. He translated Max Bauer's "Precious Stones" in 1904 and R. Braun's "Mineral Kingdom" in 1908-12, wrote "The World's Minerals" in 1911, and has contributed numerous articles on crystallography and mineralogy to Thorpes' "Dictionary of Applied Chemistry," and to the "Encyclopædia Britannica." But it is as an abstractor, editor, and indexer of mineralogical papers that Dr. Spencer has rendered especially useful service to the science. Since 1895 he has written abstracts for the Chemical Society. From 1900 until 1914 he was referee for the immeralogy volumes of the 'Catalogue of Scientific Literature' He undertook the editing of the Mineralogical Magazine in 1901, became collaborator for mineralogy and crystallography in the International "Tables annuelles de constantes et données numeriques" in 1912, and commenced the publication of Mineralogical Abstracts in 1920, the majority of the abstracts for which have been written by himself. For his earlier work he was awarded the Wollaston Fund of the Geological Society in 1902. He was elected a fellow of the Royal Society in 1925.

PROF. W. A. BONE, lecturing before the Chemical Society on Nov. 24, took as his subject "Gaseous Combustion at High Pressures" Since 1920, Prof. Bone and his junior colleagues at the Imperial College of Science and Technology have been engaged in the study of the combustion of mixtures of hydrogen, carbon monoxide. or methane with oxygen and diluent gases under considerable initial pressures; as was recently announced in NATURE, this work is shortly to be extended and amplified. Prof. Bone commenced his discourse by emphasising the actual abnormality of the conditions which man is in the habit of regarding as normal, and quoted Prof. Eddington's statement that, apart from the interstellar cloud which is at the moderate temperature of 15,000°, probably ninetenths of the matter of the universe is above 1,000,000°. "We must," he said, "keep our minds open to the reception of knowledge accruing from a study of gaseous interactions under what until recently would have been considered abnormal conditions of density and pressure." Had the pressure of our atmosphere been several hundred times what it actually is, the story of chemistry would have been rather different. The value of high pressure work hes in the fact that it accentuates the operation of influences which are either masked or overlooked at the ordinary pressure. There is a great increase in the rate of chemical change, and a proportionate decrease in cooling and dissociation effects; moreover, the increase in density of the medium may affect both the emission and the absorption of radiation during the explosion.

Bombs and other apparatus now in use at the Imperial College were described and illustrated by Prof. Bone in his lecture referred to above; the spherical bombs are capable of withstanding explosion pressures up to 2000 atm., and a cylindrical one withstands explosion pressures of 1200 atm. The latter can be fitted with quartz windows for spectrographic work, and may then be used up to 500 atm. The behaviour of theoretical hydrogen-air and carbon monoxideair mixtures is in striking contrast; the pressure in the former rises in about 0 005 sec. to 400 atm. (max ), then immediately beginning to fall, whereas in the latter the pressure takes 0 18 sec. to reach 410 atm. (max.), and begins to fall only after a considerable interval. The replacement by hydrogen of a very small proportion of the carbon monoxide enormously accelerates the pressure rise in explosions in gases initially at 50 atm. Prof. Bone also described experiments leading to the recognition of the phenomenon of nitrogen 'activation,' and dealt with the consequent

secondary production of nitric oxide in the presence of excess oxygen. The spectrographic evidence shows that steam does not function chemically, but that carbon monoxide reacts directly with oxygen in carbon monoxide-air explosions, that the radiation emitted in such direct interactions is strongly absorbed by either carbon monoxide or nitrogen, and that in a carbon monoxide-air (excess) explosion at 25 atm. initial pressure, no nitric oxide is formed during the actual explosion period, although more than 25 per cent of nitrogen dioxide may be found in the cooled final explosion products. Prof. Bone paid tribute to the devotion and skill of his junior colleagues, the late Mr W A. Haward, and Drs. D. M. Newitt and D. T. A. Townend.

At the water engineers' congress on Nov. 17, in connexion with the Public Works, Roads and Transport Exhibition at the Royal Agricultural Hall, Islington, Prof. J. W. Gregory gave a lecture upon water divining. He defined the geological problemas being why a method once used in the search for so many objects is now practically restricted to that for water, for which it is perhaps now more used than at any previous time. He explained this as due to shallow water being so widely distributed that the diviner is bound to have a large percentage of successes, while the failures are forgotten. In many cases there is no clue to such water, and the search for it must be often 'wild-catting'; men expert in the search for such water may be often particularly successful. There are three rival explanations—that the rod moves in response to a physical force, to clarvoyance, or to muscular response to the recognition, often perhaps unconsciously, by the diviner of faint clues to water. Prof. Gregory considers that the decision between these views must depend upon the evidence He discussed the chief British evidence and claimed that all the controlled experiments are against the divining rod. He referred especially to those organised by the Sanitary Record and Municipal Engineering at Guildford in 1913, to the tests by Prof. Wertheimer and Prof. Sollas, and to that for oil divining under the supervision of Sir John Cadman at the Anglo-Peisian Company's experimental station Four cases put forward as most convincing evidence for the divining rod by Barrett and Besterman were also discussed, but Prof. Gregory claims that they give no support to either the physical or clairvoyant explanation of the divining rod

"The Nile and the Use of its Waters" was the subject taken by Sir Murdoch Macdonald for his recent presidential address to the Junior Institution of Engineers. Sir Murdoch described the possibilities of land reclamation and irrigation improvements which still exist in Egypt, and explained the constructional works at present under consideration. One proposal, he said, is to heighten the Aswan dam by seven metres, and, so far as stability is concerned, it would be perfectly safe. The Gebel Aulia site for a new dam and reservoir in the White Nile just beyond Khartum is an excellent position, and a relatively low dam built on the sandstone formation would be capable of keeping in a large volume of water. Other suggested

sites for dams are at Lake Tsana and Lake Albert-To meet all the demands of Upper and Lower Egypt for reclamation and irrigation, the summer supply of the river must be increased to about 1500 tons per second, with correspondingly greater volumes during the other periods of the year. Account must also be taken of developments in the Sudan, but the Sudan area is too restricted to take such a quantity of water from the Blue Nile as would harm Egypt. Sir Murdoch said that there is conjoined with all these works, and others which may yet be suggested, a political aspect, but if the builders of all or any of them do not forget the rule that the right of first user to water can not be taken away, that it is a right which can not be separated from the property to which it applies, then justice would be done in the distribution of water to all the inhabitants of the Nile Valley, and the immemorial position in this respect of Egypt in the lower part of that valley would be fully conserved

SIR J. C. W. REITH writes an interesting article on the connexion between the State, the people, and broadcasting, in the Nineteenth Century for November. He points out that we are accustomed to associate controversy with heated crowds, exaggeration, misrepresentation, and general unreasonableness. We think of broadcast politics as differing only in degree and not in kind from platform politics. This, however, is not the case. From the programme department's point of view, politics of the platform type would be quite unsuitable Statesmen will find it necessary to develop a new technique of political argument. This technique will develop as the years go by, but it may be said in advance that it will derive little from classical or even from parliamentary oratory, and nothing at all from the pulpit or the · soap-box. We cannot say how far it will dare to go into a detailed exposition of facts and figures. It is idle to speculate, for the capacity of broadcasting audiences is always developing, and the type of matter acclaimed yesterday is barely conceivable to-day. The possibility of harm can only be prevented by securing a high and conscientious type of man or woman for the profession; one independent alike of the frown of the threatening tyrant and the ardour of the citizens bidding evil The essential qualification is implicit in the conception of service. The word 'fairness,' with all its unspoken connotations, may be taken as representing it in this particular sphere of action.

The publication last week of Sir Baldwin Spencer's work on the Arunta coincided, appropriately enough, with the announcement that he had been awarded the Rivers' Memorial Medal for 1927 by the Council of the Royal Anthropological Institute. This medal, which was founded in memory of the distinguished president of the Institute whose death took place while he was still in office, is awarded for work of pre-eminent merit in the field; in the case of Sir Baldwin Spencer, for the epoch-making work which he carried out in collaboration with the late Mr. F. J. Gillen among the native tribes of Central and Northern Australia.

THE Hopkins Prize of the Cambridge Philosophical Society has been awarded as follows: For the period 1912–15, to Prof. R. A. Sampson, Astronomer Royal for Scotland, for his researches on the internal constitution of the sun, on optical systems, on Jupiter's satellites, and on practical chronometry, for the period 1915–18, to Sir Frank Dyson, Astronomer Royal, for his contributions to the general progress of astronomy, and to the spectroscopy of the solar atmosphere: for the period 1918–21, to Prof. A S Eddington, Plumian professor of astronomy and experimental philosophy in the University of Cambridge, for his work on the classification of the motions of the stars, and on their structure, and on the influence of gravitation on rays of light: for the period 1921–24, to Di J H. Jeans, secretary of the Royal Society, for his work on the theory of gases, and on radiation, and on the evolution of stellar systems

On Dec. 7, Prof. Louis Dollo, Honorary Conservator at the Royal Museum of Natural History at Brussels. will attain the age of seventy years. On that day there will be presented to him a commemorative volume containing articles by fifty-five biologists, as an appreciation of his work in extending to fossils the laws that govern all forms of life. The British contributors to the book are the late William Bateson, F. A. Bather, W. T. Calman, C. Forster Cooper, H. Gadow, E. S. Goodrich, J. P. Hill, J. E. Marr, W. D. Matthew, G. E. Pilgrim, C. T. Regan, A. C. Seward, W. J. Sollas, J. Stanley Gardiner, and A. Smith Woodward. The volume will be the first of a new serial, Paloxobiologica, edited by Prof. O. Abel and published by E. Haim in Vienna.

The annual general meeting of the Decimal Association will be held at the Institution of Electrical Engineers on Tuesday next, Dec. 6, at 5 P.M. and will be open to anyone interested in promoting the adoption of the metric system of weights and measures—the international language of quantity—and decimal coinage into Great Britain. Addresses will be given by Sir Richard Gregory, the retiring president, and by Sir Hugo Hirst, who is succeeding him in that office

REFERRING to the paragraph in Nature of Nov. 19, p. 740, on the proposed Institute of Indexing, we are asked to state that the primary object of Mr. W. R. Douglas Shaw's proposal to establish such an Institute is to improve the standard of book indexes. The proposal provides for the compilation of indexes by the Institute which, however, would neither be conducted for profit nor as a trade union, but as an international fellowship of those interested in the use or production of books and indexing facilities.

In our issue of Nov. 5. p. 648, we published a review of Vol 1 of Dr. George Sarton's "Introduction to the History of Science," at the head of which appeared the names of the American publishers. We are now informed that Messrs. Ballière, Tindall, and Cox, 8 Henrietta Street, London, W.C.2, are publishing this work in the British Empire at 45s

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A temporary assistant on the scientific staff of the *Discovery* Expedition to undertake the preliminary sorting of the zoological collections—The Secretary, *Discovery* Committee, Colonial Office, Whitehall, S.W.1 (Dec. 9).

A lecturer in physics in the Egyptian University, Cairo—The Dean of the Faculty of Science, Egyptian University, Cairo (Dec. 9). An assistant in the botany department of the West of Scotland Agricultural College - The Secretary. West of Scotland Agricultural College, 6 Blythswood Square, Glasgow (Dec. 12). A controller of technical education under the Egyptian Ministry of Education-The Director, Egyptian Educational Office, 39 Victoria Street, S.W I (Dec. 14). A Government analyst and bacteriologist. Cyprus-The Private Secretary (Appointments), Colonial Office, 2 Richmond Terrace, Whitehall, S.W.1 (Dec. 15). A professor of economics (including economic history and statistics) in the University of the Witwatersrand, Johannesburg-The Secretary, Office of the High Commissioner for the Union of South Africa, Trafalgar Square, W C 2 (Dec. 31). Eight appointments to the Forest Service of Burma—The Secretary to the High Commissioner for India, General Department, 42 Grosvenor Gardens, S.W.1 (April 7) Two first-class honours graduates for research in optics and allied studies, and in vacuum

physics, in the Research Laboratories of the General Electric Co., Ltd.—The Director, Research Laboratories, General Electric Co, Ltd, Wembley. A fulltime teacher of rubber technology at the Northern Polytechnic, Holloway—The Clerk, Northern Polytechnic, Holloway, N 7 A full-time teacher of engineering subjects and metal work at the Doncaster Technical College—The Principal, Technical College Doncaster. A lecturer in tropical sanitation and hygiene at the Liverpool School of Tropical Medicine—The Hon. Dean, School of Tropical Medicine, Pembroke Place, Liverpool. A young graduate with good general chemical and physical knowledge, preferably with some experience of the technique of colour and colour lake manufacture-The Director, Research Association of British Paint, Colour, and Varnish Manufacturers, Waldegrave Road, Tedding-

Erratum.—In Nature of Nov. 26, p. 770, col. 2, line 9. for "0 137 $d^2$ " read "0 137 $d^3$ ." The equation should thus read.  $\theta = \sqrt{6(d+0.3d^2+0.137d^3+...)}$ .

### Our Astronomical Column.

The Total Lunar Eclipse of Dec. 8.—No total lunar eclipse at a sufficient altitude for refined work is visible in England between the years 1920 and 1938. We therefore have to make the most of those that are somewhat unfavourable. The first contact of the moon with the umbra on Dec. 8 occurs at 3.52 p.m., with the moon on the horizon; totality begins at 4.54 and ends at 6.15, the moon's altitudes, as seen from London, being 9° and 21° respectively; the last contact with umbra is at 7.18; penumbral eclipse continues for another hour, but for the latter portion of it the dimming of the moon's light is too slight to be discernible.

There are two classes of observations that can be usefully made during total lunar eclipses. The first is examination of the amount of light on the eclipsed disc, and its variation in different regions. It is only the lower regions of the earth's atmosphere that have sufficient refractive power to bend the sunlight into the inner part of the shadow; these regions are liable to have their transparency affected by cloud, so that observation of the eclipsed moon gives an integrated measure of the clearness of the earth's atmosphere round the great circle that has the moon in the horizon at the time of observation. Some have tried to establish a correlation between the illumination of the eclipsed moon and the sunspot cycle, and there are advantages in considering an integrated atmospheric effect of this kind rather than the records of isolated stations.

The other useful observations to make during lunar eclipses are occultations of faint stars; the best values of the moon's semidiameter were derived from such observations. During the coming eclipse,  $\iota$  Tauri, mag. 4·7. will disappear at 4.30 P.M., P.A. 84°, and reappear at 5.19, P.A. 245°; B D. 21° 754, mag. 8·2, will disappear at 4.57, P.A. 90°, and reappear at 5.46, P.A. 238°. The latter is taken from the B.4.A. Handbook. The times are for London. The darkness of totality can also be utilised for observing comets, which are usually lost for several days about full moon.

COMETS.—The comet Schwassmann-Wachmann has now been photographed on three days at Bergedorf,

No. 3031, Vol. 1201

the following positions having been telegraphed from the I.A.U. Bureau, Copenhagen:

From these, Mr. J. Moller, of Copenhagen Observatory, has computed the following parabolic orbit:

This orbit implies that the comet passed perihelion, 18 months before discovery, and is now outside the orbit of Jupiter. It would have been near opposition at the time of perihelion, and very much brighter than it is now.

It must be borne in mind that the preliminary orbit of such a distant comet is subject to considerable uncertainty. Thus, in the case of comet Shajin-Comas Sola in 1925, the early elements differed much from the final ones. The following ephemeris, calculated from the above elements, is not likely to be much in error:

0h.	RA.	N Decl	log 🕹
Nov. 30	$1^{\rm h} 27^{\rm m} 54^{\rm s}$	20° 18′	$0.72\overline{1}1$
Dec. 8	$1 \ 26 \ 22$	20 0	0.7331
16	$1 \ 25 \ 32$	19 46	0.7457
24	1 25 25	19 34	0.7587
	1 20 20	10 04	0.4004

The Bulletin of Tokyo Observatory gives the following orbit of an object discovered there last January (designated Tokyo 1) which seems from its movement to be a comet, though its aspect was planetary.

The perihelion distance is 1.20 units, the aphelion is near the orbit of Uranus. From the moderate inclination, the object would be hable to make close approaches to Jupiter.

### Research Items.

Polynesian Religion —In Bulletin 34 of the Bernice P. Bishop Museum of Honolulu, Mr E S. Craighill Handy has published an extensive study of the essential elements of the belief and practice characteristic of the ancient worship of Polynesian peoples, the result partly of three years literary research, partly of five years personal investigation in the different island groups of Polynesia. On analysis it appears that the religions of the various island groups at the time of their discovery were of a composite An ancient foundational system is fundamentally related to the culture as a whole, and is most pronounced in the large island groups on the periphery. Hawan, the Marquesas, and New Zealand. It is termed Indo-Polynesian because the sources are to be found in regions long dominated by Indian religious influence. Second in importance is the region in which Tangaloa was regarded as supreme being, a region nearer the centre of recent cultural evolution, namely, Samoa, Tonga, and the Society Islands. Later intrusions or borrowings come from Melanesia and America, the Melanesian coming by way of Fiji and Tonga, or by borrowings of Polynesian voyagers, the American by the borrowing of Polynesian adventurers who found their way to Mexico and Peru. The Indo-Polynesian religions show traces of ancient Indic. south-east Asiatic, historic Hindu, and Chinese influ-It may be that the fusion of the first three may have taken place in south-east Asia or Indonesia before they were carried to Polynesia, while the Chinese influences may have been brought in by stray Chinese Tan-kah-lo-seafarers of the river population

'ELEPHANT HEADS' IN MAYA SCULPTURES.—Mr. J. Elic Thompson. Field Director of the British Museum Expedition in British Honduras, in an article in the Scientific Monthly for November, revives the question of the significance of the 'elephant heads' in the drawings of Maya sculptures at Palenque made by Waldeck at the beginning of the last century Waldeck unquestionably intended to portray elephants' heads and his treatment of the tapir is distinctive. Mr Thompson points out that not only is Waldeck's accuracy in other matters not above question, as is shown by reference to Maudslay's work, but also he was strongly influenced by a belief in the Asiatic origin of American culture and that this might have influenced his interpretation of an indistinct original. As the originals have since perished, the question is beyond solution one way or the other by direct evidence. Mr. Thompson summarises the arguments for and against judicially, but holds that even if the case for the elephant were proved, it would not support the diffusionists, though the attitude that America was never affected to any appreciable extent by Asiatic culture would have to be abandoned. Recent archæological research has shown that of the essential elements in the culture for which 'diffusion' is claimed, agriculture and pottery-making antedate the elephants by at least a thouasnd years.

Function of the Epiglottis.—The epiglottis is a tongue-shaped cartilaginous flap situated at the anterior border of the larynx. It used to be thought that this structure acted as a 'lid' to the larynx, falling back over the laryngeal aperture in order to prevent ingress of food or liquid during swallowing. This view was shown to be erroneous by Stuart. who proved that during swallowing the epiglottis actually moves forward and does not fall back. Moreover, when the epiglottis in man is destroyed by disease, swallowing remains unaffected, and many animals do

not possess it yet swallow periectly. Mr. V. E. Negus (Jour of Anatomy, vol. 62. Pt. 1, 1927, p. 1) now suggests that the principal function of the epiglottis is to preserve the integrity of the olfactory sense (smell) when the mouth is open; it prevents entrance of air by the mouth by apposition to a long soft palate, thus compelling the inspired air to pass through the nose. The epiglottis is best developed in deer and antelopes, animals which largely rely on powers of scent for their actual existence, and in carmivores such as the wolf and hon, which are, therefore, able to open the mouth widely and yet to preserve undiminished the integrity of their powers of scent. In some instances the epiglottis may subserve a subsidiary function in respiration and in deglutition, but not in phonation, and song birds do not possess it

COCCIDIOSIS IN CATS AND DOGS —Justin M. Andrews (Amer. Jour Hygiene, vol 6, pp. 784-798, Nov. 1926) has studied the course of infection with Isospora felis and ruolta in cats The incubation period is two to four days, and the duration of symptoms does not usually exceed a week The preparent period (from the administration of the oocysts to the appearance of the parasites in the fæces) is usually five of six days. and the patent period averaged about thirty days. There was some indication that the severity of the miection varied directly with the number of oocysts originally administered. One attack of coccidiosis seems to render cats and dogs non-susceptible to subsequent infection by the same organism. This immunity lasts for seven months, and probably for The author considers that Isospora hominis is peculiar to man, and that it occurs more frequently than has been reported.

The Luminous Organs of Watasenia —G. Shima (Proc. Imp. Acad. Tokyo, July 1927) in a note on the nature of the luminous bodies of Watasenia scintillans. refers to the three classes of luminous organs present in this squid. In one of these, innumerable rod-shaped bacteria occur in the luminous cells, and in the other two classes of organs similar bacteria occur. though in fewer numbers. A pure culture—a colony—of the bacteria of the first organ when placed in a dark chamber was found to emit light of the same nature as that produced by the luminous organs of the live squid. The part of the luminous organs of the live squid. The part of the luminous organ in which the bacteria occur gives a lipoid reaction. The author points out that luminous bacteria have been recorded hitherto in the Myopsida, but now they are shown to be present in Watasenia, which belongs to the Egopsida. In another œgopsid. Enoploteuthis chunii. the author has found similar bacteria in the luminous organs, which correspond to the second and third classes of organs in Watasenia.

The Nucleus of Amæba.—Monica Taylor, S.N.D, states (Quart. Jour. Micr. Sci., vol. 71, Pt 2; 1927) that long and careful examination of cultures has failed to reveal any trace of syngamy in the life-instory of Amæba proteus. Metcalf stated that the life cycle of this species may require a year for its completion, and this is substantiated by the present author. The development period during which the culture contains no adults or very few is followed by one during which the adults increase rapidly in numbers because of fission. The latter period may be prolonged almost indefinitely by sub-culturing, but without such interference it lasts almost six months. The nucleus of the young amæba is disc-shaped, and consists of a karyosome more or less centrally placed

in a reticulum of nucleoplasm Chromatin in varying amounts is present in this reticulum. The karyosome is a much more conspicuous object in the developmental stages than in the adult, possibly because in the latter the chronatin blocks under the nuclear membrane arrest attention. The deeply staining portions of the karyosome in both young and old amoba contain chromatin and the latter passes out at intervals to the nucleo-reticulum, gradually making its way to the periphery as the nucleus grows in size, so that in adults ready to form encysted young the karvosome appears to consist of a vacuolated reticulum of nucleoplasm. When the nucleus is fully adult the chromatin of the periphery becomes subdivided into patches, large and not regular to begin with, but later forming 'blocks' These blocks are therefore bits of the karyosome which in turn give rise to the chromatin blocks that escape into the cytoplasm of the agamont and form the karyosomes of the agametes. The author concludes that the rudiment of the nucleus in a developing A proteus is wholly karyosomic and remains so throughout the encysted condition.

THE THEORY OF SAND DUNES —A new development in the theory of sand dunes is made by Dr. Vaughan Cornish in a recent paper on "Waves in granular material formed and propelled by winds and currents (Geophysical Supplement. Monthly Notices, R.A.S., July 1927, pp 447-467). It refers to waves in ridges. the crests of which are not level but undulating, with alternate peaks and saddles. Since the formation of these has been observed during a period of constant wind, the phenomenon cannot be regarded merely as a complication due to veering winds: it is a definite dynamical feature of the final stage of dune development in an unconsolidated material. It is natural to expect that collapse will occur, in a series of steep sand-waves transverse to the wind, if the current increases too quickly, and also that breakdown will take place first at special points, determined by accident; what requires explanation is the persistence of the peaks which remain after such breakdowns  $\mathbf{D}_{\mathbf{I}}$ Cornish finds evidence, from the form and size of the small ripples on the windward slopes of the ridges. indicating that over the windward face of the peaks there is a confluence of the winds towards the saddles, and that the convergence results in a spinning movement that increases the scouring action in front of the saddles. On the lee side of the ridge, the finer particles carried in the vortex may be deposited behind the peaks, though in some cases it was found that deposition occurred behind the saddles, the ground immediately behind the peaks being at a lower level

CONTINUOUS X-RAY SPECTRA.—One of the outstanding problems in connexion with the production of X-rays, that of the origin of the continuous spectrum, has been studied by W. Duane in an investigation described in the September number of the Proceedings of the National Academy of Sciences. A modified Coolidge bulb was built in which the effective target was a small volume of mercury vapour at low pressure. This was excited by a homogeneous beam of electrons the energy of which was just insufficient to remove the L electrons, whilst the softer M rays produced were unable to pass through the mica observation window of the tube. The feeble intensity of the resulting pencil precluded the use of a spectrometer, and its average wave-length had therefore to be found by measurement of the absorption coefficient in aluminium. Quoting from one set of results, the average wave-length was 1 10 A., whilst that corresponding to the applied potential was 1.04 A., a difference of only 6 per cent. The conclusion drawn from these and similar data is that in at least a large number of im-

pacts the electron transfers the greater part, if not all, of its kinetic energy into radiation, and that the latter is nearly, if not exactly, monochromatic

Electrification by Friction —In a communication to Nature, Mr. W A Macky, of University College, Auckland, gives a preliminary account of his experiments on the effect of the pressure of the surrounding gas on the electric charge produced by rubbing together a metal disc 2 cm in diameter and The metal disc. an insulating disc 3 cm in diameter of aluminium or steel, was connected to an electroscope with a condenser in parallel and the readings of the instrument were taken on separating the discs atter their flat surfaces had been rubbed together by rotating the disc of insulator. As the pressure of the gas was reduced, the readings of the electroscope fell for discs of glass, sulphur, and ebonite, from 100 volts at atmospheric pressure to 2 or 10 volts at less than a centimetre of mercury, while for discs of silk or chamois, the fall was only to about 75 volts. Similar affects were found in air, oxygen, to be aware of the work of McClelland and Power, or of the theory of Riecke) When the insulator disc was of glass, any faulty insulation caused the reading of the electroscope to increase to amounts of the order of 850 volts when the rubbings were repeated without the discs being discharged. This effect the author ascribes to the charge on the insulator disc leaking to the back surface and therefore not taking part in the withdrawal of the charge from electroscope and condenser when the two discs are brought together. The electroscope in consequence shows a residual charge, to which rubbing adds the normal charge, and as a result the total is increased.

SUPERCONDUCTIVITY.—Superconductivity was the name given by Onnes to the peculiar type of electrical conduction which is exhibited by certain metals at the extremely low temperatures obtainable by the use of liquid helium He found that the electrical resistivity of certain metals as, for example, mercury, tin, and lead, decreases at first uniformly as the temperature is lowered The resistivity then decreases less rapidly until the critical temperature is reached, when it suddenly drops to less than  $10^{-12}$  times its value at It was also found that if the specimen at  $0^{\circ}$  Kelvin a temperature less than the critical temperature was placed in a magnetic field and the field was gradually increased, the resistance became normal at a certain critical value of the magnetic field. It was further found that if the specimen were immersed in a bath the temperature of which was maintained at a value somewhat less than the critical temperature, then when the current in the specimen was gradually increased, the resistance of the specimen suddenly became normal for a certain value of the current. In 1917, Silsbee made the suggestion that this critical current and the critical magnetic field were not independent phenomena. It is highly probable that the threshold current is that which produces a field equal to the critical magnetic field. Onnes and his associates did a large amount of experimental work the results of which support this hypothesis. In Scientific Paper No. 556 of the Bureau of Standards, Silsbee makes a detailed analysis of the experimental results got at Leyden. His results support the assumptions on which his theoretical work is based.

Radio Direction-finding.—The Department of Scientific and Industrial Research has issued a special report (No. 5) on radio direction-finding by Dr. R. L. Smith-Rose (London: H.M. Stationery Office; 1s. 9d). It summarises the progress that has been made in this

direction during the last five years. A comprehensive survey of the subject is given and the results obtained during the last two years are included. A theoretical discussion on broad lines is also given. This proves the notable contribution which the study of directionfinding has made to the solution of the important problem of the propagation of radio wave- round the The explanation of the propagation of radio waves round the earth as merely a phenomenon of diffraction presents many difficulties. A partial explanation can be made by making the hypothesis of a conducting layer in the atmosphere. Eckersley showed that while the transmission of vertically polarised waves by the conducting layer was sufficient to explain the measured values of radio signal strength. it was necessary to assume that the down-coming waves at the receiving end contained a horizontally polarised component in order to explain the variations in the apparent bearings observed on direction-finders. Experiments strongly confirm this theory. As the result of the intensive research being carried out in various parts of the world on the propagation of radio waves, the mechanism of the actual deflexion from the ionised layer is rapidly being placed on a satisfactory quantitative basis. The author concludes that the appreciable errors which occur when using the direction-finder at night are caused by the down-coming waves polarised with the electric force horizontal. As a direct result of the theoretical analysis, a system of direction-finding has been developed in which the night errors to which all closed coil systems are apparently hable have been reduced to a negligible amount.

A New Cathetometer. - The cathetometer is a laboratory adjunct of which the cost is usually much more impressive than the range of accomplishments. A pattern recently produced by Messrs. Casella, of 49 50 Parliament Street, Westminster, therefore disturbs a tradition. This instrument is not only strikingly versatile, but also, strangely enough, is being put on the market at a much lower figure (£26) than its more simple predecessor. The central vertical column, supported by a heavy flat tripod with adjustable feet. is present as in the earlier type, but the telescope carriage, instead of travelling thereon, rides upon two of the three vertical brass rods which form a sort of cage rotating about the central column. One of these rods is engraved with a scale of 1 metre divided into millimetres and readable by vernier to 0 05 mm. The carriage can slide freely or may be rigidly clamped at any height on the scale, it can also be adjusted by fine motion sciews for height and level. Similarly, the cage can rotate freely, may be rigidly clamped to the central shaft, or may have its motion finely controlled. The central column has a head and levelling screw, so that the whole apparatus may be laid horizontally. In this position the apparatus will serve as a reading telescope for use with a balance or galvanometer, or it may be used as a comparator of length, either by means of its accessory mountings, for end gauges, or, by changing the object glass, for measures of length.

The Surface Tension of Molten Metals and Alloys—The surface tensions of molten tm, bismuth, cadmium, lead, zinc, and antimony have been redetermined by Yosiharu Matuyama by a dropping method (Science Reports. Tohoku Imperial University, vol. 16, No. 5, June 1927, p. 555)—At the melting points the values in vacuum for the six metals are 591, 401, 67.9, 479, 800, and 375. The surface tension falls linearly as the temperature is raised, the values at 600° C being for the first five about 51 6, 350, 602, 432, and 755. The constant in Eotyos equation

connecting the surface tension with temperature is tound to vary from 0.9 to 1.2 for tin, bismuth, lead, and zinc. The method has been applied to the three allov systems, cadmium-antimony, zinc-antimony, and lead-antimony. In each case the tension falls from that of the metal with the higher value to that with the lower on a fairly gentle curve, rapidly at first and later more slowly. In the two former systems, however, there are small breaks at compositions corresponding with the compounds CdSb and Zn<sub>3</sub>Sb<sub>2</sub>. The conclusion drawn is that these compounds do not dissociate consoletely on fusion

THE CRYSTAL STRUCTURES OF AMMONIUM, POTAS-SIUM, AND RUBIDIUM CUPRIC CHLORIDE DIHYDRATES. In the September issue of the Journal of the American Chemical Society, S. B. Hendricks and R G. Dickinson describe the results of an investigation of the crystal structures of the compounds R2CuCl4.2H2O, where R represents ammonium, potassium, or rubi-The study of salt hydrates and ammoniates by the methods of X-ray analysis is, in general, rendered difficult by their low crystallographic symmetry, and this case was no exception. Laue and spectral photographs were used and their interpretation necessitated a very careful examination of reflection intensities. For each of the salts, the structural unit contains two R2CuCl4.2H2O and is based on a simple tetragonal lattice. Each copper atom is immediately surrounded by two oxygen and four chlorine atoms, two of the latter being at a distance from the copper 0.75 A. greater than the distance of the other two. Each alkalı atom is surrounded by four oxygen atoms, four copper atoms and eight chlorine atoms. The inequality of the two copper to chlorine distances is naturally assumed to indicate that the copper exerts different forces on the two pairs of chlorine atoms, and this fact, together with the behaviour of these compounds in solution, seems to show that they are of the double salt rather than the complex salt type. In the case of K2CuCl4.2H2O the dimensions of the structural unit were found to be  $d_{100} = d_{010} = 7.45$  A. and  $d_{001} = 7.8$  A.

A STUDY OF THE STRUCTURE OF THE SURFACE OF ORDINARY SOLUTIONS .- A long contribution on this subject describing work carried out by J. W. McBam and G. P. Davies has just appeared in the September issue of the Journal of the American Chemical Society. As compared with the large amount of data for films of insoluble materials resting on the surface of a solvent such as water, very little is known about the structure of the surfaces of solutions. The determinations of Donnan and Barker of the absolute adsorption of a substance from true solution at the air interface, using nonylic acid solution, are thought to be inaccurate, and an improved method is described. The adsorptions per square centimetre of surface of aqueous solutions of p-toluidine, camphor, and amyl alcohol are given, and these amounts are considerably in excess of those required for a monomolecular surface film. It is suggested that, in addition to a monomolecular film, there is an excess concentration in the immediate neighbourhood of the surface and chains of oriented molecules extend inwards into the solution. The authors point out that this conception affords an explanation of some other results. numerical results obtained are in disagreement with Cabbs's formula, and the authors use the strict thermodynamic formula of Gibbs, taking into account all the components present, even the gas in contact with the surface. It is also considered essential to include terms not in the Gibbs equation in order to allow for the electrical effects which occur at all surfaces.

### Synthetic Formaldehyde.

FORMALDEHYDE, which is greatly in demand for disinfection and for the manufacture of artificial resms and synthetic dyes and drugs, was at one time chiefly imported into Great Britain as a 40 per cent aqueous solution (formalin) at a price which stimulated investigations into the possibility of its synthetic production. Since it is made by the catalytic dehydrogenation of methyl alcohol, usually over a copper contact mass, its price will naturally be dependent on that of wood spirit, and hence on the demand for wood charcoal, unless alternative supplies of the alcohol become available, as is now in fact the case. The falling exports of wood distillation products from the United States of America, and the large natural sources of gaseous hydrocarbons within the Empire, are facts which mdicated clearly enough the direction in which research should be undertaken. The Chemistry Research Board of the Department of Scientific and Industrial Research consequently decided to explore the possibility of the economical production of formaldehyde by the oxidation of hydrocarbons.

The work was carried out at the Royal Naval Cordite Factory, Holton Heath, Dorset, and is the subject of a report entitled "The Production of Formaldehyde by Oxidation of Hydrocarbons" (Chemistry Research, Special Report No. 1) by Messrs. W. Ledbury and E. W. Blair, which has just been published by H.M. Stationery Office (2s. net) This report deals both with the production of the formaldehyde and with its recovery from aqueous solutions. Although the account of the investigations shows that the formaldehyde can be manufactured according to the proposed process in the form of a dilute solution, it is pointed out that the commercial success of the method has been forestalled by a greater success: that of the manufacture of methyl alcohol ('methanol') from

mixtures of carbon monoxide and hydrogen By this means the price of formaldehyde has been reduced from £130 to £40 per ton, and even the United States of America is importing from Germany supplies of this commodity

Valuable information, however, has been gained in connexion with the concentration of dilute formal-dehyde solutions, and the Board has wisely decided to place on record the whole of the data. The Report first describes the production of formaldehyde by the controlled oxidation of ethylene, methane, etc., much of the work has already been published in detail, and is therefore familiar to those interested in the subject. The Report covers the transition of the laboratory experiments to semi-technical processes; the use of coal gas has also been examined, but the cost was found to be prohibitive except during emergency periods. A semi-technical investigation of the absorption by water of dilute formaldehyde vapours is next described, and reference is made to the bisulphite and ammonia compounds of formaldehyde.

The section on the recovery of formaldehyde from aqueous solutions commences with a description of a laboratory investigation of the distillation of formaldehyde solutions at atmospheric pressure, followed by the results of large-scale tests, and experiments on distillation under pressure and continuous distillation. Incidentally, it was found that iron, even in the form of an alloy containing only 9 per cent. of that metal, is unsuitable for use in the construction of stills for formaldehyde solutions on account of its activity in causing decomposition of that compound, whilst nickel, aluminum, and copper are non-reactive. The cost of concentration appears to be such that it is uneconomical to concentrate by distillation a solution appreciably weaker than 1.5 per cent.

### History of the Desert Flora of the Old World.

DETAILED analysis of the systematics and distribution of various typical desert plants of central Asia has led the Russian botanist, M. G. Popov, to some very interesting general considerations on the origin and history of the desert flora of the Old World (Bull. Univ. Asia Centrale, Tashkent, livr. 15, 1927, pp. 239-292)

According to Popov's views, the primitive desert flora developed so early as in the Cretaceous, or even the Jurassic period. To this time must belong such forms as Welwitchia, Ephedra, etc., and the centre of origin must have been in the central parts of the Gondwana continent. Destruction of the latter resulted in the shifting of the main desert area into the southern hemisphere, where a continuous landmass existed during the Cretaceous period and a free exchange of desert forms between South Africa, South America, and Australia could take place. During this period such great groups of desert plants were developed as Zygophyllaceæ, Geraniaceæ, Rutaceæ, Capparidaceæ, etc., and for this complex of forms the author proposes the name of the Welwitchia flora.

At the same period the African continent was connected by the Lemurian with India, and over this bridge desert forms from South Africa migrated through the Deccan into central Asia, while northward migration of the desert flora on the African continent itself went so far north as the southern shores of the sea of Thetis, which occupied the place of the Sahara. Thetis separated the region of the Welwitchia flora from more northern parts of the Arctogæa, where a

very different mesophilous flora, which originated on the Angara continent, developed

Parallel with the migration of purely desert elements from South Africa northwards, there was an interchange of less xerophilous plants between western Asia and South Africa, by way of East African table-lands; in this way Erica, for example, migrated from south to the north, and Dianthus in the opposite direction. The disappearance of the Lemurian bridge separated the South African desert region from Asia, while the lowering of the East African mountains resulted in its separation from the Mediterranean deserts.

A further stage of the development was due to the disappearance of the Thetis sea, in place of which the vast desert belt stretching from Sahara to Mongolia developed. These deserts were invaded by the Welwitchia flora which already flourished on the southern shores of the Thetis. In this way the very uniform ancient Mediterranean flora was formed, and its further evolution consisted in extensive interchange of forms with America, by way of the Northern Atlantic. This, together with the dying-out of many ancient elements of the Welwitchia flora in the Palæarctic deserts, owing to changes of edaphic conditions, led to further changes in the flora of the latter now entirely separated from the South African desert region. As a result, a special desert flora was evolved, which may be called ancient Mediterranean, or Iranian, but its history is to be discussed in a later paper by the same author.

### Anniversary Meeting of the Royal Society.

GIR ERNEST RUTHERFORD, in his presidential address at the anniversary meeting of the Royal Society on Nov 30, referred to the scientific careers and work of the twelve fellows and three foreign members who died during the year. Among other subjects surveyed in the address are the publications of the Society and the attendance at the ordinary meetings. Sir Alfred Mond, on behalf of Imperial Chemical Industries, Ltd., has offered a subscription of £1000 a year until further notice to help to meet the deficit on the publication account, in substitution of that of £500 a year for three years made by Messrs Brunner, Mond and Co. in 1925, and the Council has gratefully accepted the gift. Since the War there has been a notable increase in the number of papers published by the Society. This is specially marked in the 'A' Proceedings, where, in place of one volume a year before the War three or four volumes now appear, the separate numbers being issued with proinptness and regularity '

As one means of increasing the interest, and therefore the attendance, of fellows at the incetings of the Society, facilities have been provided for the display of experiments or demonstrations in the tea-room

before and after the reading of papers

We print elsewhere in this issue Sir Ernest Rutherford's remarks upon the results of investigations carried out in recent years to produce intense magnetic fields and high voltages for general scientific purposes; and we subjoin extracts from descriptions of the work of this year's medallists.

#### Presentation of Medals.

THE COPLEY MEDAL, AWARDED TO SIR CHARLES SCOTT SHERRINGTON.

Sherrington early chose as the special field of his investigations the physiology of the central nervous system. To this, during some thirty years, he has steadily devoted his great skill in experiment, bringing the immense complexities of its function within the range of objective analysis, and revealing fundamental plan and orderly sequence in the reflex actions by which it controls the activities of the body, and continuously adjusts them to the environment. The results of this work have been embodied in a series of some two hundred original memoirs, presenting a continuous record of progressive investigation. The earlier stages have been brought under review and treated synthetically by Sherrington in his now famous Sillman Lectures on 'The Integrative Action of the Nervous System.' In these he deals with the occurrence and significance of the muscular rigidity which appears when the higher brain is removed, with the co-ordination of muscular movements by reciprocal excitation and inhibition of antagonistic muscles. with the rhythmical, phasic activity which the conflict produces in the centres concerned with certain movements, and with the appearance of a purposeful character which the integrating action impresses on many forms of reflex response The influence of Sherrington's investigations has spread far beyond the limits ot his own laboratory and has inaugurated a new era in neurological investigation throughout the world.

## A ROYAL MEDAL, AWARDED TO PROF. JOHN CUNNINGHAM MCLENNAN

For more than thirty years Dr J. C. McLennan has been an industrious and enthusiastic experimenter, his papers being mainly concerned with radioactivity, gaseous conduction of electricity, the spectra of the elements, and the liquefaction of gases. Among

his works of outstanding merit may be mentioned the measurements he has made with his pupils on the fine structure of spectral lines which are of much importance to modern theories of the mechanism of the Recently he has had quite sensational success in tracing to its source the elusive auroral line \5577. an extremely difficult task which had baffled the skill of many previous investigators. This is important not only in itself but also on account of the information it yields as to the structure of the upper atmo-Apart from his own private researches he has built up a most efficient school of physics in Toronto. and is largely responsible for the present strong position of physical science in Canada. He has devoted much energy to the establishment of a cryogenic laboratory in Toionto, a heavy task which he has carried out with much success.

#### A ROYAL MEDAL, AWARDED TO SIR THOMAS LEWIS.

From 1911 onwards to the present day, Sir Thomas Lewis has taken a leading part in the remarkable growth of our knowledge of the mammalian heartbeat, which has been one of the conspicuous scientific achievements of the period in question. Lewis s researches enabled him to locate the point of origin of the beat, and to plot out the course of the wave of excitation over the ventricles and anticles of mammals. By extending these observations to the hearts of representative vertebrates, he was able to compare the modes of spread of the wave with the special forms of the electrocardiagram, and thus to appreciate clearly the meanings of the several deflexions. Further extension to diseased hearts led to the interpretation of the abnormalities of the electrocardiagraphic record

In 1911 Lewis was able to show that, as Cushny had previously suggested, certain cardiac irregularities are due to fibrillation of the auricles; and his later clinical and experimental work on auricular fibrillation and flutter suggest that the irregularities are due to the formation of an endless circulating wave of contraction in the auricles. Quite recently he has published the results of investigations of the peripheral circulation, upon which he has been engaged during the past

twelve years.

## THE DAVY MEDAL, AWARDED TO PROF ARTHUR AMOS NOVES

Prof. Noyes's researches have been chiefly concerned with the properties of solutions, in particular of electrolytic solutions. Soon after the inception of the electrolytic dissociation theory of Arrhenius, it was recognised that all was not well with the strong electrolytes. Whilst qualitatively their properties were accounted for by the theory, there yet existed marked quantitative discrepancies. Accurate measurement of the properties of such solutions was the first requisite for the attack of the problem, and to this task Noyes applied himself. His investigation of the conductance of aqueous solutions up to temperatures as high as 300° forms a classical example of exact physicochemical measurement executed under conditions of great experimental difficulty.

His work on the influence exerted by one salt on the solubility of another, on transport numbers and the mobilities of the ions, on the ionisation of pure water at different temperatures, is all directed to the same end. Noyes showed the importance of the classification of the strong electrolytes according to their valency type and, more than twenty years ago, attempted to take into account the electrostatic forces between the ions. He thus foreshadowed the modern

amongst other workers.

#### THE BUCHANAN MEDAL, AWARDED TO DR. MAJOR GREENWOOD

Dr. Greenwood is specially distinguished for the statistical study of medical subjects, having applied the statistical method to the elucidation of many parablems of physiology, pathology, hygiene and epidemiology. He has been pre-eminent in encouragmg and developing the use of modern statistical methods by medical laboratory investigators and in securing the adequate planning and execution of field investigations. He is almost unique in the possession of both the medical knowledge and mathematical ability which are essential in these researches.

### THE HUGHES MEDAL, AWARDED TO DR WILLIAM DAVID COOLIDGE

Science is under a great debt to Di. Coolidge for the invention and production of a new type of X-lay tube, called by his name, of great flexibility and power, which has proved of great service not only to medical radiology but also in numerous scientific researches In the last few years he has applied his unrivalled technical knowledge to the generation of high-velocity cathode rays, which can be passed into the air through a thin window as in Lenard's pioneer experiments thirty years ago. Such researches are of great importance to science, as they promise to provide us with new methods of obtaining a copious supply of swift electrons and high-speed atoms of matter for experimental investigations.

### University and Educational Intelligence.

CAMBRIDGE -Mr. G E. Wherry has been elected to an honorary fellowship at Downing College Mr H A. Roberts, Secretary of the Appointments Board, has been elected to a tellowship at Gonville and Caus College Mr F. C Phillips has been elected to a fellowship at Corpus Christi College

Prof Nuttall, Magdalene College, has been re-elected Quick professor of biology. Mr. F. C Bartlett, St John's College, has been reappointed reader in experimental psychology. Miss M. S. Willis, Girton College, has been appointed demonstrator in geography.

It is proposed to add the Astronomer Royal, the Hydrographer of the Navy, the Director-General of the Ordnance Survey, and the Chief of the Geographical Section of the General Staff at the War Office to the committee for geodesy and geodynamics.

LONDON.-Prof. E. C. Williams, who has held the Ramsay Memorial chair of Chemical Engineering at University College since 1923, has resigned in order to occupy an important post in the Shell Oil group. His business will be the active development of the group's research organisation in California. Prof. Williams, who was a distinguished graduate and scholar of the University of Manchester, was employed for five years by the British Dyestuffs Corporation, and for one year as research chemist to the Joint Committee of the University of Leeds and the National Benzole Association At University College, in temporary buildings, he has conducted courses of instruction on lines which he described in an inaugural address at the College in 1924. His work has been remarkably successful, and abundant evidence is forthcoming of the advantages gained by students who have added to their ordinary university curri-culum in chemical science a period of study in the Ramsay Department of Chemical Engineering. The measure of success achieved has encouraged the

theory now so widely developed by Noyes himself | College to an immediate and considerable develop-A very strong and inment of the Department fluential committee has been formed for the purpose of collecting a building and endowment fund, with Sir Alfred Mond as chairman, Sir R Waley Cohen as vice-chairman, Sir David Milne Watson as honorary treasurer, and Sir Frank Heath as honorary secretary

The title of professor of chemistry in the University has been conterred on Dr J. F Spencer, in respect of the post he holds at Bedtoid College Prof. Spencer studied at University College, Liverpool, and at the University of Bieslau Since 1905 he has worked in the Department of Chenustry at Bedford College; in 1915 the title of reader in physical chemistry was conferred on him, and since 1919 he has been head of the department His published work includes "The Metals of the Raie Earths" (1919), "An Experimental Course of Physical Chemistry," "The Magnetic Susceptibility of some Binary Alloys (with M E. John, Proc Roy Soc, A, 1927), and numerous papers in chemical journals

A course of five free public lectures on "The Technique of Bacteriological Research" will be given by Mr. F. W. Twort, at the Royal College of Surgeons of England, on Dec. 5, 7, 9, 12, and 14, at 4 o'clock.

OXFORD -Sir Edward Farquhar Buzzard, of St. Thomas's Hospital, Physician Extraordinary to the King, the newly appointed Regius professor of medicine, is well known as the author of numerous treatises upon diseases of the nervous system. He was one of the first of a highly talented succession of medical men at Magdalen College, including Drs. Jex-Blake and Golla of St. George's, Dr Huist of Guy's, Dr. Singer and Sir Bernard Spilsbury. He has also filled the office of secretary of the Royal Society of Medicine.

The wing of the Engineering Laboratory, recently completed, was open to the inspection of a large party of guests invited by the Vice-Chancellor and Prof. Jenkin on Nov. 24. By this addition, much-needed space will be found for the electrical equipment of the . laboratory. Demonstrations were given of the methods of using the various testing machines

An examination for the Radcliffe Travelling Fellowship, for which women are now also eligible, will commence on Feb 14, and candidates are requested to send in their names to the Regius professor of medicine on or before Feb 1, 1928.

THE King has consented to open the new buildings of University College, Nottingham, which have been given by Sir Jesse Boot, probably some time in July

SIR JAMES CURRIE, formerly Principal of the Gordon College at Khartum and Director of Education in the Sudan, has been appointed chairman of the governing body of Imperial College of Tropical Agriculture, in succession to Sir Arthur Shipley, who died on Sept. 22 last.

The Committee of Award of the Commonwealth Fund Fellowships announces that it is now prepared to receive applications for the fellowships to be awarded in 1928. Last year there were 115 candidates, and 22 appointments were made. The fellowships are normally tenable at an approved American university for two years, and are open to persons of British birth domiciled in England, Scotland, Wales, and Ireland, who are graduates of recognised universities and are unmarried, and not more than thirty years of age. Women as well as men may apply. Provision amounting approximately to £600 per annum will be made for the total expenditure involved during the tenure of a fellow-hip. Applications must be forwarded through the authorities of the university of college of which the candidate is, or was, a member. The form of application can be obtained from the Secretary to the Committee, Mr. R. H. Simpson, 50 Russell Square, London, W.C.1. Applications must reach the Secretary by Feb. 18 next.

COURSES in anthropology of the University of Pans for the coming session announced to open in December or early in January offer the usual wide field to the student. At the Instaut d'Ethnologie. among the lecturers in courses for the diploma and certificate are M. Mauss (ethnology), M. Rivet (anthropology), and the Albe Breuil archéotogic evolution There are also courses of instruction in linguisties, biological and zoological anthropology quaternary geology and paleontology and the physiology of man and the anthropoids. Under the Faculty of Higher Education a great variety of subjects is offered in preparation for the examination of the Institut d Ethnologie, the lectures being distributed among various of the constituent institutions of the University They cover ethnology. archæology, sociology, human geography, linguistics and phonetics, physical anthropology, and human palæontology and geology. As usual, special attention is given to the culture and languages of the natives of the French possessions both in Africa and the Farther East

Ax address on "The Royal Society of Aits its Services to Trade and Training was delivered on Nov. 2 by Sn Philip Magnus, who has succeeded Sn Thomas Holland as chamman of the Society's council. The admess has just been published in the Society's journal Sir Philip shows clearly that the "Society for the Encouragement of Arts, Manufactures, and Commerce," as it was called when it was founded in 1754, has kept its original purpose steadily in view. Until the middle of the nineteenth century the method chiefly used was the award of prizes of money and medals for discoveries and inventions. Whilst encouraging applications of science to commerce, it strove to discourage commercialism among men of science, restricting the grant of its prizes to those who published their discoveries for the public good. This ban on patented inventions was withdrawn in 1844. About this time the Society, impressed by the value of the evening technical classes provided by the Mechanics Institutions, took a leading part in the formation of a union of these bodies, and in this connexion initiated exhibitions of educational appliances. It was as an adjunct to these activities that the Society's examinations, now an important factor in the organisation of commercial education in Great Britain, were started in 1854 Originally designed on a comprehensive plan, including many non-technical subjects, the scheme was remodelled in 1876 so as to exclude all except subjects closely connected with trades and crafts. and was further restricted in 1879 to commercial subjects. To-day, with candidates numbering between sixty and seventy thousand, its examination system is the biggest in the world. Its value as an educational factor is now to be investigated by a departmental committee appointed by the Board of Education to inquire as to it and other systems of examination of part-time students "with particular reference to the place and value of examinations as an element in training for industrial, commercial, and professional activity.

### Calendar of Discovery and Invention.

December 4 1827—Though the Admiralty had possessed stramboats from 1822, the first commissions for the command of steam vessels ever granted to haval orners were those signed by the Duke of Clarence, then Lord High Admiral, on Dec. 4, 1827, when HMSS Lightning, Meteor, and Echo were commissioned by Lieuts, Evans, Bullock, and Hay, respectively. This official recognition of steam vessels as auxiliary waiships may be said to mark the birth of the steam Navy of Great Britain.

December 5, 1879 —Among those who extended the use of the camera in astronomy was Sir William Abney Beginning his experiments on the chemical action of ied and infra-red rays in 1874, he obtained a substance sensitive to these rays and with it explored a vast unknown and ever-invisible region of the solar spectrum. his map of which was pre-ented to the

Royal Society on Dec. 5, 1879.

December 7, 1820 — Davy was first elected president of the Royal Society in 1820, and his presidential address was read on Dec. 7. His address was entitled Discourse on the Present State of the Royal Society and on the Progress and Prospects of Science," and it contained much respecting Davy's own views on science.

December 8, 1610.—One of the earliest users of the telescope was the English algebraist. Thomas Harriot, who in 1609 made sketches of the moon and later observed the newly found satellites of Jupiter. Harriot is also remembered for his observations of sunspots, which began on Dec. 8, 1610; from them he determined the sun's axial rotation.

December 8, 1864 — Maxwell, after taking his degree in 1854, read through Faraday's "Experimental Researches, and from that time adopted Faraday's conception of a medium as a guide throughout his electrical investigations. One of his earliest papers was "On Faraday's Linesof Force," read in 1855, but his great paper, "On a Dynamical Theory of the Electromagnetic Field," was read to the Royal Society on Dec. 8, 1864. In this, electromagnetic action was shown to travel through space at a definite rate in waves, and these waves to consist of disturbances which are transverse to the direction in which the waves were propagated "Nine years later, Maxwell expanded his work into his well-known." Treatise on Electricity and Magnetism.

December 8, 1874—Few astronomical phenomena have been looked for so eagerly or prepared for so assiduously as the transit of Venus of Dec. 8, 1874. Many methods for its examination were studied, some four score posts of observation were provided, and the expeditions cost nearly a quarter of a million sterling. The chief aim of the astronomers was to improve the determination of the sun's distance, but it was afterwards said, "As regards the end for which it had been undertaken, the grand campaign had come to nothing."

December 9, 1813 — The honour of making the manufacture and sale of gas a commercial success belongs to Samuel Clegg, the first chief engineer of the London and Westminster Chartered Gas Light and Coke Company. On Dec. 9, 1813, he took out a patent for a gas meter, and he also made the first large gasometer and invented the first pressure regulating device.

December 10, 1845—The original inventor of the pneumatic tyre was the Scotch engineer. Robert William Thomson, who on Dec. 10, 1845, patented a leather tyre with an internal rubber tube filled with air. He afterwards fitted such tyres on road carriages

### Societies and Academies.

#### LONDON

Royal Society, Nov. 17—T. Graham Brown: Absence of a linear relationship between graded simple reflex flexions and the relations thereof evoked by a constant extension producing stimulus. In decerebrate cats, graded flexion magnitudes of simple flexor shortening are obtained in response to flexion-producing stimuli of different intensities. Each of these simple shortenings is then subjected to the 'inhibitory' effect of a constant extension-producing stimulus—thus giving compound flexor shortening. Comparison of the magnitudes of simple flexor shortening and of compound flexor shortening fails to establish a linear relationship between the two.

T. Graham Brown Absence of a linear relationship between the reflex flexor shortenings evoked by a graded series of flexion-producing stimuli and the inhibitory' lengthenings of a constant extension reflex evoked by the same stimuli. In decerebrate cats, graded reflex magnitudes of simple flexor shortenings are obtained in response to flexion-producing stimuli of different intensities. Each of these stimuli is then compounded with a constant extension-producing stimulus, and the resultant lengthening (relaxation) of the extensor muscle is measured. Comparison of the magnitude of simple flexor shortening and of compound extensor lengthening fails to establish a general linear relationship between the two.

T. Graham Brown: The relation of the magnitudes of remaining reflex shortening in two antagonistic muscles during compound stimulation. Where two antagonistic reflex stimuli are applied concurrently, the remaining shortenings of two antagonistic muscles during compound stimulation are related to each other. This relation is such that in many cases where one or both of the reflex stimuli are varied in intensity, the sum of the remaining shortenings in the two antagonistic muscles (each measured as a ratio to maximal reflex shortening) is constant. In other instances this constancy fails, but a series of sums bears an approximate relationship of linearity to the magnitudes of the simple reflex shortenings evoked by the series of graded reflex stimuli which are used in the experiment. The most general statement of this relationship is as follows: The sum of the proportional remaining shortenings in two antagonistic muscles, Y, is linearly related to the simple reflex shortening, X, evoked at each intensity of the series of graded reflex stimuli used in a series of compound reflexes, i.e. Y = AX + B.

Sybil Cooper and D. Denny-Brown: Responses to stimulation of the motor area of the cerebral cortex. The spinal discharge evoked by cortical stimulation can follow the rate of repetition of break shocks in that stimulus up to about 180 a second, indicating a very simple synaptic relation between the pyramidal tract and the anterior horn cell. Rates of stimulus above and below that rate usually cause a total electro-myographic rhythm of 160 to 180 a second. Varying types of grouping of the spinal discharge occur, among them being that of a 'dominant' rhythm of 35 to 50 a second, with no relationship to the rate of stimulus. The typical motor response to stimulation of the motor area shows signs of concurrent inhibition. Clonic after-discharge, 'epilepsy,' and the form of the motor response are the result of a conflict between inhibition and excitation.

J. Lorrain Smith and T. Rettie: The distribution of lymphatics defined by autolysis of their contents. Autolysis post mortem of the liquid contained in the lymph forms doubly refractile globules of 'soap,' often in such quantity that the lumen of the channel is

filled continuously. Lymphatics of the liver are defined because in them the globules form abundantly and at a stage when, as yet, no sign of them is to be found in any other site.

Geological Society, Nov 2.—J. A. Douglas and W. J. Arkell. The stratigraphical distribution of the Combrash. I. The south-western area. The stratigraphical distribution of the Cornbrash in south-western England, from Oxford to the south coast near Weymouth, is described, and the eleven brachiopod zones proposed by Mr. S. S. Buckman are discussed. The new records are added to Mr. Buckman's faunal range-diagram, and in this way it is shown that many of his conclusions regarding penecontemporaneous erosion and non-sequences in the Cornbrash, as expressed in his clinal diagram, have been based on insufficient data. A twofold rather than a threefold subdivision of the Cornbrash is advocated.

Linnean Society, Nov. 3 .- R. W. T. Gunther: Exhibition of rotographs of some unpublished letters of John Ray The letters were written by Ray to the. antiquary, John Aubrey, and to the Keeper of the Ashmolean Museum, Edvard Lhwyd, between 1676 and 1703 It is proposed to print them *in extenso* as an extra volume in the Ray Society's series, together with Ray's letters to the secretaries of the Royal Society.—T. A. Sprague: The botany of Brunfels. Brunfels' interest in plants seems to have been chiefly confined to their medicinal properties, on which his classification was largely based, with the result that some of his 'genera' were highly artificial; 'Scrophularia,' for example, included Scrophularia nodosa, Sedum Telephium and Ranunculus Ficaria. His use of the terms 'male' and 'female' sometimes indicated differences in flower-colour between two plants which were otherwise more or less similar, the deeper colour in the following order—red, blue, yellow, white-being 'male,' and the paler colour 'female' The term 'female' in other cases indicated a spurious kind or an abnormality. His herbal contains the first recognisable illustrations of many of the Lunnean species, of which indeed they may often be regarded as the historic types.—S. K. Mukerji: The biological relations of Mercurialis perennis L. The known range of M. perennis has been considerably extended, and the discontinuity in distribution of the genus is more apparent than real. Seed output is low compared with many other woodland species, and only about 10 per cent. of the seeds formed in England are germinable. The root-system shows branched and unbranched roots, both infected with fungi, particularly the former. Shallow rooting is associated with very high water content of soil, and the lower the acidity the deeper the penetration. Great variation in leaf form and size occurs. The leaf margin bears hydathodes secreting an acid liquid containing potassium chloride and calcium carbonate. An intergradation of sex has been observed. Pollination is partly entomophilous but mainly anemophilous. The fruit explosively ejects the seeds to a distance of about 4 metres. M. perennis shows no correlation between dry weight and the total carbonate content of the soil, and it is apparently not a true calcicole but an oxyphobe. It shows decided preference for soils with a high organic content. Light intensity distinctly affects the distribution and growth of individuals of the different sexes separately, and light intensity may determine the sex of a plant under certain conditions.

Optical Society, Nov. 10.—J. R. Hamblin and T. H. Winser: On the resolution of gratings by the astigmatic eye. An investigation of the resolution of gratings by the human eye, commenced by H. H. Emsley in 1925, is continued. The irregular curves

representing variation of grating acuity from meridian to meridian is of the same general form in all astigmatic eyes. Experiments show that the images of gratings placed in various directions, which are produced by an ordinary astigmatic system, show irregularities of the same form due to the overlapping of the blurred images of the separate lines of the gratings. Thus an eye with regular astigmatism will exhibit irregularities in resolving gratings at various inclinations, and charts consisting of fine parallel lines are not trustworthy for testing ocular astigmatism.

Physical Society, Nov. 11.-G. W Sutton: The power-factor and capacity of the electrodes and base of triode valves, with special reference to their use in thermionic voltmeters. A discussion of the conditions under which a three-electrode valve-voltmeter should be operated to ensure a minimum power consumption, and at the same time to give indications closely proportional to the square of the input voltage; and a sumple method of adjusting the operating voltages to fulfil the necessary conditions.—H. Lowery: (1) The refraction and dispersion of (1) air, (2) oxgven, (3) gaseous chloroform; (2) New determinations of the gaseous refractivities of (1) acetone, (2) methyl ether, (3) ethyl ether The refractivities of air, oxygen and gaseous chloroform have been found for the green mercury line ( $\lambda 5461$ ), and the dispersion studied over the range \4800 to \6700. The gaseous refractivities of acetone, methyl ether and ethyl ether for λ5461 have also been measured.—Panchanon Das: The theory of the elastic pianoforte hammer. By making various approximations, formulæ are obtained from which it is possible to deduce the practical effect of the elasticity and velocity of the hammer, and of the position of its point of impact on the string.

#### EDINBURGH.

Royal Society, Nov. 7.—A. W. C Menzies and P. R. C Macfarlane: Some further notes on the salmon of the River Moisie, Eastern Canada. Moisie catch is chiefly composed of salmon which have spent either 2 + or 3 winters in the sea, and one of the main features of interest is the high proportion of 'spring' fish which arrive in June and July—83 per cent. in 1923 and 41 per cent. in 1924. Grilse apparently are almost entirely absent from the Gulf of St. Lawrence rivers (only one was found in this Moisie collection), although they are present in large numbers in Newfoundland, and, apart from the two age groups already mentioned, the catch is composed almost entirely of fish on their second or third return to the river: 13 per cent. in 1923, and no less than 29 per cent. in 1924 belong to this last class of fish, which consequently form a proportion far beyond that usually found in European rivers. The average weight of the Moisie large spring fish, 20.5 lb., is much the same as that of similar fish on the eastern side of the Atlantic. but the weight of the 2 + winters group, 10.5 lb., is only comparable with that of the earlier of the migrants of the same history in Great Britain. Recovery after spawning is evidently rapid and growth is good. Only one-third of the smolts were two years old at migration, and the remainder were either three or four years of age.—L. H. Easson and R. W. Armour: Action of 'active' nitrogen on iodine. Experiments on the rate of the reaction between active nitrogen and iodine vapour and on the intensity of the light emitted for different pressures of rodine. emission of the line 185  $\mu\mu$  was observed and the evidence for the energy content of active nitrogen discussed.—J. W. Gregor: The pollination of Lolium perenne and L. stalicum. The prevalence of selfsterility in the agricultural grasses has indicated

methods of breeding, and an investigation of this problem was necessary preparatory to the study of the survival of growth forms within wild populations. It has not been possible, so far, to increase the selffertility of L perenne and L. italicum by changing the environmental conditions, or by artificial methods of pollination. The results obtained from plants under strictly controlled conditions have been confirmed by growing these plants in the field isolated from other plants of the same species.—Dorothy J. Jackson: Wing dimorphism in the genus Sitona and its inheritance in Sitona hispidula F. (Coleoptera, fam. Curculionidæ). Wing dimorphism is common in the genus Sitona and has been specially studied in S. hispidula. In the macropterous form of this species the wings are fully developed. In the brachypterous form the wings are small and truncated, and the metathorax is modified in structure. The dimorphism is well-marked in the pupal stage. Some of the macropterous insects are capable of flight, others have the wing muscles greatly reduced and histologically The macropterous and brachypterous abnormal. forms are widely distributed in Europe and occur frequently in the same locality. Breeding experiments conducted to determine the genetical relationship of the two forms indicate that the brachypterous condition is inherited as a simple Mendelian dominant.— B. Kaczkowski: Contribution to the studies of the origin of European sheep. Craniological investigations on the sheep having been found unsatisfatory, the method of serological isoagglutination was applied in an attempt to discover the ancestral types involved in the development of modern European sheep. Two main blood groups are present in sheep; one (A), as found in O. musimon and in Polish local sheep, being dominant to the other (O), as found in the Southdown. The latter group may be divided into two sub-groups, one with, the other without, anti-A. It would appear probable that differences in origin exist between the English Southdown and the Polish local sheep.—E. T. Copson: On Fourier constants. By the use of a theorem recently proved by Titchmarsh, certain convergence properties of series of Fourier constants are obtained. The results are connected with the generalised Riesz-Fischer and Parseval theorems, but cannot be obtained by the use of these.

#### MANCHESTER.

Literary and Philosophical Society, Nov. 1.-J. N. Langdon and Edna M. Yates: Transfer of training in manual dexterity. The doctrine of transfer of training states that training in any specific form of mental activity is capable of having its effects transferred to any other activity of the same form although dealing with different material. A group of 32 subjects was trained intensively for a fortnight, in a laboratory adaptation of a process employed in driving-chain manufacture. Tests of manual dexterity and muscular ability were given before training was commenced and at the ends of the first and second weeks respectively. The same tests were given to a group of 28 subjects who received no training. All the subjects were of roughly the same age and type, and in each case the subject's payment was calculated upon actual performance, hence the predominant incentive to satisfactory performance was a financial one and may be assumed to be constant. Statistical analysis of the results reveals that there is no significant difference between improvement in the test performances of the trained and control groups respectively. In fact, the brief practice afforded by the first giving of the test is more effective than the prolonged intensive training on a similar, but not identical, performance. There is evidence, then, that training in manual dexterity is specific and not general.

#### SHEFFIELD

Society of Glass Technology, Oct. 19.-J. F. Hyslop: Crystal growth and impact brittleness. The chief cause of brittleness in opal glass is the tendency of the glass to produce sharp angular crystals, and these may be formed by. (a) the tendency of the matrix to precipitate silica. If the opal is susceptible to this secondary devitrification, a careful choice of working temperature is necessary to avoid brittleness; (b) the tendency of the glass to grow angular instead of globular fluoride particles. This happens in a glass of low viscosity, and such a glass is brittle at low and high working temperatures.—E J. C. Bowmaker and J. D. Cauwood The detection of selenium in decolorised bottle glass. The glass is treated with hydrofluoric acid, a little strong nitric acid, and evaporated to dryness at about 90°C. Strong nitric acid is added to the residue, again evaporating to dryness. The residue is then dissolved with 1 · 1 nitric acid and a little water added Strong sulphune acid is added and the whole evaporated until fuming. After cooling, a piece of codeine sulphate is added with stirring, and the solution heated to furning A green coloration denotes the presence of selenium. Manganese and copper must be absent.

#### PARIS.

Academy of Sciences, Oct. 31.-Ch. Depéret: New observations on the neolithic deposits of Glozel (Allier). The authenticity of the deposits described by the author last year has been disputed. New excavations were made last July, in company with MM. Arcelin and Bjorn, of the Oslo Museum, under conditions which would render impossible the fraudulent introduction of objects. The author concludes that the date of the Glozel deposits dates from very early Neolithic and maintains the authenticity of the discoveries.—A. Lévèque. The theoretical solution of the problem of the exchange of heat by circulation of a non-viscous fluid in quiet movement, with velocity potential, inside a tube—A. Schidlof: The interpretation of the masses of the electron and proton in a universe of five dimensions -Boutaric and Mile. G Perreau: Refractometric measurements on colloidal solutions. Results of the application of the interference refractometer to colloidal solutions, especially the phenomena accompanying flocculation. — A. Travers. The ionic equilibrium  $Al(OH)_3 + 6F \rightleftharpoons AlF_6 + 3OH$ . Cryolite is stable over a wide range of pH.— Joseph Péneau: The age of the iron minerals attributed to the Gothlandian in the synclinal of Saint-Julien-de-Vouvantes.—Maurice Piettre: Remarks on agglutinating immunosera localisation of the agglutinines.-Henri Jean Frossard: The treatment of deafness by the Laennec method.-A. Leulier, P. Sedallian, and J. Gaumond: Diphteric toxin, nucleoproteids, and dialysis.

### ROME.

Royal Academy of the Lincei, June 19.—L. Palazzo: Results of a magnetic exploration in the Giuba and Uebi Scebeli (Southern Somaliland).—P. Vinassa: The 'electronic number 'and constituents of the globe. The electronic number, indicating the number of peripheral electrons which can be found in the various elements taking part in terrestrial combinations, seems to be not merely of geochemical interest, as it serves as the basis of a new classification of the elements.—C. Foà: The neurochemical mechanism of vagal inhibition in the heart of mammifers. The results of experiments on frogs indicate that stimulation of the cardiac vagus does not determine distance phenomena, and that the presence in the blood of a substance with

vagal action may be assumed .- L. A Herrera: Plasmogeny. Imitation of amœbæ by means of resin soap — S. Minetti · The Taylorian development  $\sum a_n z^n$ , where  $a_n = g(n)$  with g(n) wholly transcendental Laboccetta. Equations of geometrical figures comprising a parameter with variation of which the line or surface represented passes continuously from the polygonal or polyhedral form to the circular or spherical form.—P Nalli and G. Andreoli The area of a surface, Stieltjes' multiple integrals, and multiple integrals of functions of several complex variables.-G. Krall · Green's functions relating to pluri-connected fields.—F. Robles · Rayleigh's theorems of small oscillations -G Thomsen. Dynamics of rigid bodies in general relativity —A Masotti. Motions of a perfect liquid by plane strata —A. Carrelli The hydrodynamic interpretation of the quantum theory.— Gold purple. G. R. Levi and C Fontana supposedly cubical granules of gold in purple of Cassius have a side with the mean value 36 A. Addition of stannic acid has no influence on the degree of subdivision of the gold —G Malquori · The system,  $Fe(NO_3)_3 - KNO_3 - H_2O$  at 25°. Nonohydrated ferric nitrate and potassium nitrate form neither additive compounds nor mixed crystals at 25°. The solubility curves of the two salts project beyond the point of intersection, a metastable region being thus exhibited. —G. Natta: Crystalline structure of cassium trichloromercurate. This compound, CsHgCl<sub>2</sub>, obtained by crystallisation of the solution containing excess of cæsium chloride, crystallises in the monometric system. The elementary cell is cubic, the side being 5.44 A. The positions of the ions in the cell are defined by the following co-ordinates: Hg  $(\frac{1}{2},\frac{1}{2})$ ; Cs  $(0\ 0\ 0)$ ; Cl  $(\frac{1}{2},\frac{1}{2}\ 0)$ ,  $(0\,\frac{1}{2},\frac{1}{2})$ ,  $(\frac{1}{2}\ 0\,\frac{1}{2})$  The calculated density is 4.53.—A. Rejna. Crystalline structure of calcium hydroxide. For this compound the values given by Levi, namely. a = 3.52, c = 4.93, c : a = 1.40, are confirmed, the value  $u - \frac{1}{4}$  being assumed and the co-ordinates for Ca and O being Ca  $(0\ 0\ 0)$ ,  $0\ (\frac{1}{3}\ \frac{2}{3}\ u)$ :  $(\frac{2}{3},\frac{1}{3},u)$  —L. Scremin · Variations in the ionic equilibrium as factors of pharmacological action Potassium and convulsant drugs. When the equili-, Xa-Kbrium  $\frac{r_{a-1}}{Ca^{-1}Mg^{-1}}$  is modified in the sense of an increase in K+, the cells of the posterior cornu react far more

readily towards drugs which have the specific effect of mcreasing the reflex excitability. The cause of this action of the potassium ion is not known, but it may be due to the fact, observed by various investigators, that this ion renders the cell-walls more permeable and thus facilitates the entry of the drug.—P. Aloisi: Study of the manganiferous pyroxenes. Examination of two samples of Italian rhodonite reveals a variation in the sign of the double refraction with change of the relation between the manganese oxide and the oxides of other bivalent metals. This variation in sign appears to be accompanied by profound modifications in the whole orientation of the indicatrix.—A. Desio: Miocene echinoderms of Porto Bardia and of the oasis of Giarabub.—B. de Finetti: Conservation and diffusion of Mendelian characters. (11) General case. -E. Benedetti: Modifications in the course of alcoholic fermentation arising from the effect of the oscillating electromagnetic field on the yeast. When either 5 per cent. glucose solution or beer wort containing yeast is subjected to the action of an oscillating electromagnetic field for a short time, the velocity of the subsequent fermentation is diminished. As the action of the field is prolonged more and more, this effect increases to a maximum and afterwards changes to an acceleration of the fermentation, this again changing to a retardation for still longer exposures to the field.

No. 3031, Voj. 1201

### Official Publications Received.

The New Zealand Astronomical Society (Incorporated) Bulletin No 3 1. Do we Live in a Spiral Nebula: by P O'Dea, in . I the Universe in a State of Cosmic Equilibrium' by F Gawith. Pp 19 Bulletin No 4 The Interior of the Earth and its relation to the Surface Features By P. O'Dea Pp 18 (Wellington, N.Z.) Proceedings of the Royal Society of Edinburgh, Session 192-1,27 Vol 47, Part 3, No 20 Tie Theory of Orthogonants and Latent Roots from 1881 to 145 By Sir Thomas Mun. Pp. 272-252 (Edinburgh Robert Grant and Son, London, Williams and Norgate Ltd.) 28 61 Seventh Annual Report of the Scientific and Industrial Research Council of Alberta, 1928. (Report No 20) Pp 58. (Edmonton, Alba., W.D. MacLean)

Council of Alberta, 1926. (Report No. 20) applied. Council of MacLean;
W. D. MacLean;
The Royal Technical College, Glasrow Annual Report on the One Hundred and Thirty-first Session, adopted at the Annual Meeting of Governors held on the 18th October 1927. Pp 74. (Glasgow.)
International Commission on Illumination Brief Report of the Bellagi) Meeting, 31 August—3 September 1927. Pp 23+2 plates (Teddington National Physical Laboratory) 2s., 50 cents

### Diary of Societies.

#### SATURDAY, DECEMBER 3.

ROYAL SOCIETY OF MEDICINE (Otology Section), at 10 a m — S. Hastings and G. R. Scarff. Some Notes on Paracusis William from the Ferens Institute of Otolarymgology.—Dr. D. McKenzie Posterior (Mastord) Dramage in Acute Supplication of the Middle Ear Royal Institution of Great Bertain, at 3.—G. Holst. Samuel Wesley and Robert Pearsail (III)
Institute of British Foundamen (Lancashire Branch) (at College of Treinology, Mauchester), at 4—E. Longden. Foundry Practice in the United States of America.
Institute of Chemistry (Manchester and District Section) (at Manchester)—Address by Chairman.

chester) -Address by Chairman.

#### MONDAY, DECEMBER 5.

MONDAY, DECEMBER 5.

CAMBRIDGE PRILOSOPHICAL SOCIETY (in University Chemical Laboratory), at 4.30 — Dr. E. K. Rideal. The Electron Work Function and Surface Action — W. H. Mills and K. A. C. Elhott. Molecular Dissymmetry Dependent on Restricted Rotation about a Single Linking. The Optically Active Forms of Renzenessiphonyl.8-nitro-1-naphthyliglycine. — To be communicated by title only — Dr. F. G. Mann. Note on the Configuration of the Tetrammino-platinous Complex — Prof. E. T. Whittaker: Note on the Law that Light rays are the Null Geodesics of a Gravitational Field — Miss M. D. Kennedy: Two Sets of Conditions for Expansion in a Laurent's Series. — S. Pollard: A. Condition for Inverting the Order of Integration in a Repeated Integral.—Dr. F. Bath: On the Quintic Surface in Space of Five Dimensions.

ROYAL SOCIETY OF EDINBURGE, at 4:30—Prof. E. T. Whithker: The Induence of Gravitation upon Electric Phenomena—Prof. C. G. Darwin. The New Outlook on the Mechanics of the Atom—To be read by the maly—Miss Nellie B. Eales. The Anatomy of a Fostal African Elephant, E., no. appearant (Lo obonia arrindna). Part 2. The Body Muscles—Prof. H. W. Turnball. The Invariant Theory of the Quaternary Qualitatic Complex. 1. The Reduced System.
VICTORIA INSTITUTE (at Central Hall, Westminster), at 4:30.—Dr. J. A. Fleming. Minner in Nature and in the Biblical Literature indicating a Common Origin in a Supreme Intelligence.
ROYAL INSTITUTION OF GREAT BRITAIN, at 1—General Meeting.
BRITISH PSychological Society (Education Section) (Annual General Meeting) (at London Day Training College), at 5:39—At 6:15—D. W. Oates. An Experimental Study of Tenjerament.
Society of Engineers (at Geological Society), at 6.—Dr. W. Rushton: The Preservation of the Parity of River Water with Regard to Pisciculture.

culture

In Preservation of the Parity of River Water with Regard to Pisciculture
Institution of Althomobile Engineers (Western Centre) (at Merchant Venturers' Technical College, Bristol), at 0.45 —Prof. Browning: Pinking and Dopes
Institution of Electrical Engineers (Informal Meeting), at 7—
N.E. Jackson and others. Discussion on An Heating and Conditioning.
Royal Society of Arts, at 8.—Prof. H. C. H. Carpenter. Aloy Steels, then Manufacture, Properties, and Uses (Cantor Lecture) (IV.)
Society of Chemical Industry (London Section) (at Chemical Society), at 8.—Dr. H. S. Hatheid Automatic Aralysis of Liquids and its Application to Control of Wart Softening Plants.
Royal Geographical Society (at Eolian Hall), at 8.30.—Major J. C. Cooper Cark and G. Laws. Lubantum
University of Birmingham Chemical Society (Birmingham University)—Prof. T. M. Lowry: Rec. at Advances in Stereochemistry.
Institution of the Rubber Industry. (Undon Section) (at Engineers' Club, Coventry Street, W.).—W. W. Hamili: Efficiency Methods in the Rubber Industry.

### TUESDAY, DECEMBER 6

ROYAL INSTITUTION OF GREAT BRITAIN, at 515 -Sir William H. Brage A Year's Work in X-Ray-Crystal Analysis (III)
INSTITUTE OF MARINE ENGINEERS, at 030 -Sir Westcott S Abeil. The

INSTITUTE OF MARINE ENGINEERS, at 6 30 —SH Westcott S Adent the Story of the Ship Institution of Electrical Engineers (East Midland Sub-Centre) (at University College, Nottingham), at 647—D S. Munro Modern Electrical Wilmig as applied to Small Houses.

Electrical White as applied to Small Houses
ROYAL PHOTOGRAPHIC SOCIETY of GREAT BRITAIN (P. total Group),
at 7—A C Bandeld: Some Odds and Ends from the New World
INSTITUTE OF CHEMISTRY (Edinburgh and East of Scotland Section)
(JOULDY with Society of Chemical Industry—Edinburgh and East of
Scotland Section) (at 36 York Place, Edinburgh), at 7-30.—Sir James
Walker. Electro synthesis
North-East Coast Institution of Engineers and Shipbuilders
(Middlesbrough Branch) (at Cleveland Scientific and Technical Institution, Middlesbrough), at 7-30.
INSTITUTE OF MITALS (North East Coast Local Section) (at Armstrong
College, Newcastle-upon-Tyne), at 7-30.—J. E Newson. Hot Extrusion
Process.

Process.

QUEERTT MIGROSCOPICAL CLUB, at 7:30—Dr. H. M Leake Some Aspects of the Plant in Relation to Disease.

INSTITUTION OF ALTOTOBLIE ENGINEERS (at Royal Society of Arts), at 7:53—W A. Whatmough Control in Carbination.

ROYAL ANTEROPLICATION INSTITUTE at 8:30.—Dr. A. C Haidon: Notes on the late R B. Deacons Investigations in Malekula, New Hebrides.

ROYAL SOCIETY OF MEDICINE (Orthopædics Section), at \$30 -G Jefferson, Dr. G Riddoch, Dr. B Shirrs, G Stebbing, and St J. D Buxton: Discussion on Fractures of the Spine

### WEDNESDAY, DECEMBER 7.

GLASGOW UNIVERSITY ALCHEMISTS' CLUB (in Glasgow University), at 859.—Debate
ROYAL INSTITUTE OF PUBLIC HEALTH, at 4.—Dr L. R Lempriere
The Health of the Public School Bov
ROYAL SOCIETY OF MEDICINE (Surgery Section) (at St. Thomas's Hospital).
at 4.—Demonstrations

at 4.—Demonstrations
'EWCOMEN SOCIETY FOR THE STUDY OF THE HISTORY OF ENGINEERING

AND TFOHNOLOGY (at Institution of Mechanical Engineers), at 530 —
J W Hall: Making and Rolling Iron (Presidential Address).
INSTITUTION OF CIVIL ENGINEERS (Informal Meeting), at 6 — Dr. H.
Lapworth: The Effect of Pumping Operations on Underground

Waters

INSTITUTION OF ELECTRICAL ENGINEERS (Wireless Section), at 6—R H. Barfield The Attenuation of Wireless Waves over Land

INSTITUTION OF AUTOMOBILE ENGINEERS (Branford Branch) (at Belle Vue Hotel, Bradford), at 7—F. H Paul' Design and its Effect on Maintenance Charges

Society of Chemical Industry (Glasgow Section) (jointly with Edinburgh Section, Institution of the Rubber Industry, and the Institute of Chemistry) (at Cad' One Restaumant, Glasgow), at 7—Dr. D F. Twiss. Sulphur in Rubber Manufacture—C Chapman. Naphthas and their Uses.

INSITUTION OF ELECTRICAL ENGINEERS (Tags. Side Sub Central (et Class)

Institution of Electrical Engineers (Tees-Side Sub Centre) (at Cleveland Technical Institute, Middlesbrough), at 7—H Pateison: Chairman's Address

man's Addifess
INSTITUTION OF HEATING AND VENTILATING ENGINEERS (at Caxton Hall), at 7.—E. A. Alliott: Institution Laundries.
INSTITUTE OF METALS (Swansea Local Section) (at Thomas' Cafe, Swansea), at 7.—R. Genders. Entrusion.
INSTITUTION OF SANTIARY ENGINEERS (at Caxton Hall, Westminster), at 7.—G. T. Cotterell The Use of Reinforced Concrete in Waterworks and Sawagos

7.—G. T. COULETEIL THE USE OF ACHITOCOC CONTROL AND SEWAGE.

SOCIETY OF PUBLIC ANALYSTS AND OTHER ANALYTICAL CHEMISTS (at Chemical Society), at 8—H Toms. Oil Bromide Films and their Use in Determining the Halogen Absorption of Oils—G. Middleton

No. 3031, Vol. 1201

and F C. Hymans: Tests for Impurities in Ether —Dr H J Stern Arsenic in Coated Papers and Boards —Demonstrations.—Apparatus for Determining Benjoic Acid in Foods, by Dr G W Monier-Williams; Sodium Flame for Polarimetric Work, by T McLachlan and A W Middleton
Royal Society of Aris, at S—S J Duly The Damage to Cargo due to 'Ship's Sweet'
Extravological Society of London at S.—Prehendary Gound G. G.

ENTENDEDGICAL SOCIETY OF LONDON at S.

EUGENICS SOCIETY (at Linnean Suc ety), at S.—Prebendary Gough G. G.

Coulton, and others D. Sastious Pinlanthropy

SOCIETY OF CHEMICAL INDUSTRY (Nottinguam Section) — Prof. R

RODINSON 'The Indole Gloup of the Alkaloids

INSTITUTION OF MICHANICAL ENGINEERS (Liverpool Branch) (jointly
with Liverpool Engineering Society)—H Gutteridge, Modern Port-

land Cement Plant

ROYAL MICROSCOPICAL SOCIETY (Biological Section)

#### THURSDAY, DECEMBER 8.

ROYAL SOCIETY, at 430 —R W James and E M Firth An X-ray Study of the Heat Motions of the Atoms in a Rockalt Crystal — I Waller and R W. James On the Temperature Factors of X-ray Reflection for Solium and Chloring in the Rocksalt Crystal —To be read I Waller and R. W. Janes. On the Temperature Factors of X-ray Reflection for Solium and Chlorine in the Rocksalt Crystal.—To be need in title only.—G. Nonhebel, J. Colvin. H. S. Patterson, and Dr. R. Whytlaw-Gray. The Coagulation of Smokes and the Theory of Smoluchowski.—P. I. Dee: The Moudity of the Actinium A. Recoil Atom measured by the Cloud Method.—A. C. Menzies. Shifts and Reversals in Fuse Spectra.—Prof. C. G. Parwin. The Electron as a Vector Wave.—W. Sucksmith, H. H. Picttei, and L. Broadway. The Magnetic Properties of Single Crystals of Nickel.—Prof. L. N. G. Filom. On the Second Approximation to the 'Oseen' Solution for the Motion of a Viscous Fluid.—Prof. C. V. Raman and K. S. Krishnan. A. Theory of the Optical and Electrical Properties of Liquids.—E. W. R. Steace and F. N. G. Johnson. The Solubility of Hydrogen m. Silver.—Dr. R. L. Smith-Rose and R. H. Barheld. Fuither Measurements on Wireless Waves received from the Upper Atmosphere.—Dr. F. H. Constable Spectrophotometric Observations on the Growth of Oxide Films on Iron, Nickel, and Copper.—J. W. Lewis. An Experimental Study of the Motion of a Viscous Laquid contained between two Coavial Cylinders.—C. E. Inglis: Oscillations of a Bridge caused by the Passage of a Locomotive.—G. R. Goldsbrough: Tides in Oceans on a Rotating Globe.—W. F. Sheppard: The Fit of a Formula for Discrepant Observations.—J. Taylor. On a Photoelectric Theory of Sparking Potentials.—Prof. G. G. Darwin: Free Motion in the Wave Mechanies.—Prof. A. Fowler The Spectrum of Phorime (F. I).—Lord Rayleigh: (a) Series of Emission and Absorption Bands in the Mercury Spectrum; (b) The Line Spectrum of Mercury. Occurrence of the Forbidden Line A2270.—W. H. Taylor and J. West. The Crystal Structure of the Chondrodite Series.
Royal Profographic Society of Medicine (Balneology Section), at 5.30.—Dr. W. Davies: Samuel Hyde Memorial Lecture
Royal Profographic Society of Reat Britain (Colour Group—Informal Meeting), at 7.—F. J. Trition: Demonstration of Tiree-colour Carbro.

Carbro.

INSTITUTION OF ELECTRICAL ENGINEERS (Dundee Sub Centre) (at University College, Dundee), at 7:30.—R. J. Lawson A. Description of Modern Telegraph.

OPTICAL SOCIETY (at Imperial College of Science), at 7:30.—Instructor Capt T. Y. Baker. The Design of Reflecting Prisms.

INSTITUTE of METALS (London Local Section) (jointly with Institute of British Foundrymen) (at 83 Pall Mall), at 7:30.—W. A. C. Newman Structostance.

Strip Casting.

ROYAL SOLETY OF TROPICAL MEDICINE AND HYGIENE (at 11 Chandos Street, W.), at 8.15.—Dr W Fletcher: Recent Work on Some Malayan Fevers.

INSTITUTION OF MECHANICAL ENGINEERS (Yorkshire Branch) (at Leeds) — J. H. Barker Chairman's Address, INSTITUTION OF MECHANICAL ENGINEERS (Western Branch) (at Bristol) — W. A. Stainer Chairman's Address, Oil and Colour Chemists' Association.

#### FRIDAY, DECEMBER 9.

INSTITUTION OF WATER ENGINEERS (at Geological Society), at 10:30 a v — Capt. W. N. McClean: Rainfall and Flow-off, River Garry, Inverness-shire.—S R. Raffety: Underground Water Supplies, and the Need for Investigation of the Sources thereof.—J. W. Madeley: Failure of Slow Sand Filtration in Madras City.

ROYAL SOCIETY OF ARTS (Indian Meeting), at 4:30—Sir David T Chadwick: The Indian Tariff Board: Discriminating Protection in Practice.

Practice.

Chadwick: The Indian Tariff Board: Discriminating Protection in Practice.

BIOCHEMICAL SOCIETY (in Imperial College of Science, Metallurgy Theatre, Royal School of Mines, South Kensington), at 4.45.—H. Henderson Smith, M. Hume, and I. S. MacLean: On the Presence of Vitamin A and Provitamin D in Yeast Fat.—W. J. Morgan and R. Robison: Dephosphorylated Methylhexosides derived from Hevose-diphosphoric Acid.—J. Pryde and E. T. Waters: Organic Phosphates from Rabbit's Muscle.—H. R. Hewer, H. Jairam, and S. B. Schryver: The Chemical Changes Taking Place in the Proteins of Muscular Tissue when Passing into Rigor.—H. J. Holman and S. B. Schryver: The Basic Hydrolysis Products of Certain Plant Proteins, and the Method of Separation.—E. J. Candlin and S. B. Schryver: The Belationship of Pectin to Hemicellulos.—E. C. Grey Studies on the Nutrition of Pigeons.—R. K. Christy and W. Robson. Estimation of Chlorides in Biological Finids.

ROYAL ASTROSOMICAL SOCIETY, at 5.—Dr. J. Evershed: The Solar Rotation and the Einstein Displacement derived from Measures of the H and K Lines.—W. M. Smart: The Constants of the Star-streams from the Groningen Proper Motions.

Paysical Society (at Imperial College of Science), at 5.—H. P. Walmissiey: The Scattering of Light by Individual Particles in Smokes.

A Mailley: On the Construction and Standardisation of an Interferomatics Pressure Gauge.

MALACOLOGICAL SOCIETY OF LONDON (at Linnean Society), at 6
INSTITUTION OF MECHANICAL ENGINEERS (Informal Meeting), at 7—
Wajor S. J. Thompson Economics in Engineering
NORTHE - EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS
(Informal Meeting) (at Newcastle-upon-Tyne), at 7 15—C W Cairns
and others: The Relation between the Drawing Office and the Shipyud and Engine Works
JUNIOR INSTITUTION OF ENGINEERS, at 7 30—T G Rose Management

Graphies
INSTITUTE OF METALS (Sheffield Local Section) (at Sheffield University), at 7:30—Prof C H Desch Stresses in Non Ferrous Castings.
OIL AND COLOUR CHEMISTS' ASSOCIATION (Manchester Section) (at Milton Hall, Manchester), at 7:30—Prof A. G Green The Application of Methods of Dyestuff Analysis in the Examination of Pigments and Laboratory. Lakes.

Lakes
UNIVERSITY OF BIRMINGHAM CHEMICAL SOCIETY (Birmingham University)—Sir John Russell Chemistry in Relation to Agriculture
Society Of Dyers and Colourists (Manchester Section) (jointly with
Institution of the Rubber Industry—Manchester Section) (at Manchester)—W E Sanderson The Colouring of Cold Cured Rubber

#### SATURDAY, DECEMBER 10

ROYAL INSTITUTION OF GREAT BRITAIN, at 3 -F J M. Stratton . Recent Developments in Astrophysics (I)
Physiological Society (at Bedford College for Women)

#### PUBLIC LECTURES.

#### SATURDAY, DECEMBER 3

HORNIMAN MUSEUM (Forest Hill), at 3 30 .- C Daryll Forde: Natural

#### MONDAY, DECEMBER 5

ROYAL SOCIETY OF MEDICINE (Barnes Hall), at 5 15 —Col P. S. Lelean: The Mind and Health (Chadwick Lecture)
ROYAL SCHOOL OF MINES (Imperial College of Science), at 5 30 —Prof H Briggs The Ventilation of Mines from the Engineering Standpoint

(Succeeding Lectures on Dec. 7 and 8.)

#### TUESDAY, DECEMBER 6.

UNIVERSITY COLLEGE, at 5 15 -H. Clifford Smith . The Equipment of a Mediæval House.

#### WEDNESDAY, DECEMBER 7

Bedford College for Women, at 5.15.—Prof Mary W. Calkins Conceptions of Meaning and of Value. (Succeeding Lecture on Dec 0) King's College, at 5.30.—Dr. E. Barker: The University and the University College.

London School of Economics, at 6—R. Sloley: Office Machinery. Demonstration of the Telegraphone.

#### FRIDAY, DECEMBER 9.

East Anglian Institute of Agriculture (Chelmsford), at 7.~-W. G. Hatton The Growing of Black Currents

#### SATURDAY, DECEMBER 10

HORNIMAN MUSEUM (Forest Hill), at 3 30 -Miss M A Muriay The Legacy of Egypt

#### CONFERENCE.

#### DECEMBER 7, 8, 9.

Institution of Chemical Engineers (at Chemical Society).

Institution of Chemical Engineers (at Chemical Society).

Wednesday, Derember 7, at 5—N. Swindin Submerged Flame Combustion
Thuisday, Derember 8, at 5.—G. W. Daniels: The Design of Refrigerating
Plants—L. Chew The Practical Aspect of Refrigerating as applied
to the Chemical Industry—R J. Mitchell Electrical Automatic
Refrigerators for Domestic Use
Finday, December 9, at 5—W. J. Jones The Problem of Industrial
Lighting, with some reference to the Chemical Industry.—At 8.—R.
G. Parker, D. N. Jackman, and J. N. Vowler: Continuous Weighing
of the Contents of Vessels The Weighmeter.—A T. Green: The
Properties of Silica and Fireclay Refractories in relation to their
Industrial Usage.

#### CONGRESSES.

DECEMBER 7 AND SUCCEEDING DATES.

FIFTH PAN-AMERICAN CHILD CONCRESS (at Havana, Cuba)

#### DECEMBER 13 10 16.

International Conference on Light and Heat in Medicine and Surgery (at Central Hall, Westmanster)

Sureerry (at Central Hall, Westmusster)

Dec 13 and 14 (Section 1).—Light and Heat in Medicine and Surgery —
Dr. F. Nagelschmidt Ultra-violet and Bioluminescence —Dr. L. G.
Dufestel: Contra-indications for Ultra-violet Therapy.—Dr. F. Hernaman - Johnson . Conjoint Ultra-violet Radiotherapy and Internal Medicine.—Dr. J. Saidman. The Therapeutic Uses of Infra-red Rays.—
Dr. E. P. Cumberbutch: Recent Advances in Diathermy Treatment —
Dr. H. S. Banks: The Place of Actinotherapy in Public Health Work.

Dec. 15 (Section 2).—Scientific Research in Relation to the Practice of Actinotherapy:—Prof Leonard Hill The Ultra-violet in Sunlight-and Artificial Sources —Prof. I. M. Heilbron: Vitamin D and its Relation to the Irradiation of Foodstuffs.—Dr. F. H. Humphris. Can the Chemist and Physicist be of Use in Actinotherapy "(Section 3).—Recent Advances in Optics:—S. G. Tibbles: Light and Vision—I. Spiro: The Treatment of Certain Common Eye Diseases in the Young by General U-V Irradiation.—Dr. K. R. Smith. Eye Muscle Training.—Dr. F. W. Edridge-Green: Colour Vision.

#### The Technical Expert in the Civil Service.

N every government department, much of the work dealt with to-day involves the consideration of problems which are of a technical character, and presents, in consequence, the need for close collaboration on the part of officers belonging to the administrative, financial, and technical branches of the department. In view of the importance and, in many instances, the complexity of the technical aspects of these problems, not only is it essential that the careers offered in the technical branches of the Civil Service shall be such as to attract men of the highest standard of qualifications, but it is also necessary that the status accorded to the technical officers shall in every way be equivalent to that of the administrative officers with whom they are required to co-operate, in order that their position in the official hierarchy may correspond with the magnitude of their responsibilities, and thus effectively ensure that due weight may be given to their proposals.

When the system of recruitment by competitive examinations was extended, now nearly sixty years ago, to the superior grades of the Civil Service, the work of government departments was almost entirely administrative in character, and the State had then only very recently entered upon its responsibility as the undertaker of an important technical enterprise, the telegraphs. The number, therefore, of men with a scientific training and technical experience required in superior positions in the Civil Service was strictly limited, and, in consequence, the competitive examination system did not apply to the technical staffs. But even then it was recognised that men of a superior standard of qualifications were required for the more important positions on the non-technical side of the Civil Service, and steps were accordingly taken to provide a career in the higher division (now the administrative class) which should prove attractive to graduates of British universities; and at one time a career on the administrative side was practically the exclusive privilege of those who had entered the Civil Service by the higher division competitive examinations.

Since the termination of the War, the administrative and clerical branches of the Civil Service have been completely reorganised on the lines of the Report of the Joint Committee of the Civil Service National Whitley Council issued in \*February 1920, and in connexion with this reorganisation an assimilation of the various grades of the administrative and clerical classes of the Civil Service has

been effected; an improvement in the salary scales has, in some cases, taken place; and provision has been made for recruiting the administrative class partly by selection from inside the service. However, a proportion of the vacancies in the administrative class will, in the future, still be filled by men selected for appointment to the public service by means of an open competitive examination in the subjects embraced by the various honours courses of university institutions. Again, on the recommendation of the Asquith Committee, the salaries of the permanent heads of the principal departments of the State were, in 1920, raised to £3000 per annum, being in the majority of cases an increase of 50 per cent. on the pre-War scales

The developments which have been taking place in the activities of government departments during the past fifty years having had the effect of making administration dependent to an increasing extent on factors of a technical nature, their problems must, in many cases, be subjected even at the initiation stage to investigation at the hands of 'experts.' Further, where specialised knowledge is required, it is these 'experts' who have to work out the details; and, in the subsequent stages, the duty necessarily falls upon them to supervise the execution of schemes, and they then become responsible for much of the administrative work involved.

The altered conditions affecting the work of government departments have naturally resulted, in recent years, in a considerable increase in the numbers of the established officers of the 'expert' class. The increase between the years 1914 and 1923 was approximately 36 per cent. At the same time, a higher standard of professional knowledge has been called for and obtained. In spite of this transformation, no attempt has, however, so far been made to bring about a classification of the professional group, nor has any general scheme been introduced to provide a career on the 'expert' side equivalent to that offered to the non-technical civil Certain improvements in the salary scales of the various grades of the professional group have, it is true, taken place; the salaries of the heads of the professional and technical departments have been raised, but the increases fall far short of the proportionate improvements in the salaries of the permanent heads of the principal departments of the State mentioned earlier, and the salaries of the professional and technical chiefs are to-day approximately two-thirds and one-half only of those of the administrative chiefs. This disparity between the salary scales of the technical and non-technical staffs is carried down into the lower grades; it is not confined to the officers employed at the headquarters of government departments, but exists, although to a less marked degree, also in the cases of officers employed in the provinces.

It has further to be borne in mind that the differences in the salary scales are accentuated by the fact that promotion is normally quicker on the nontechnical than on the technical side, and, therefore, the superior positions on the former side are, as a rule, reached at an earlier age, on an average, than positions on the latter side carrying equivalent The methods of entry into the responsibilities various groups of the Civil Service differ so widely that a general comparison of the periods of time taken to reach the several salary scales of the administrative, clerical, and professional groups in the ordinary course of departmental promotion would be misleading. However, m order to provide a concrete illustration, the careers have been traced of six university graduates who entered the administrative class (old higher division) during the period 1905-1908, and an equal number of university graduates who entered the technical side of the same department, during the same period, under an open competition scheme, the average ages of the entrants into the two classes being about the same.

On the administrative side, the average time taken by these six officers to attain the salary scale £700-£900 (the maximum of which is reached after eight years in the grade) was  $12\frac{1}{12}$  years, one of these officers was promoted to an appointment on a salary scale £1000-£1200 (the maximum of which is reached after four years in the grade) 1810 years from the date of entry into the service. On the other hand, on the technical side the average time taken by the six officers to obtain their first step of promotion to the grade carrying (in London) a salary scale £450-£550 (the maximum of which is reached after four years in the grade) was 15½ years, two of these officers were promoted to the next higher grade carrying (in London) the salary scale £600-£700 (the maximum of which is reached after four years in the grade) after serving, on an average,  $18\frac{5}{12}$  years. It is perhaps not surprising, then, that of twenty-six university graduates recruited during the period 1907-10 on the technical side of the department in question, 68 per cent. should have resigned their appointments; the high percentage of these resignations seems to indicate that, in this instance, the career provided on the technical side of the Civil Service is not sufficiently attractive to university graduates.

Further, the foregoing analysis shows clearly that to undertake specialist duties of a technical character in the Civil Service results financially in the penalising of the 'expert' officers. An attempt is sometimes made to justify the inequality of the salary scales of the technical and non-technical groups in the Civil Service on the supposition that the responsibilities of the officers in these two groups are in no way comparable, the implication being that the duties of the technical group are of an order inferior to those of the non-technical group, but no reasoned or satisfactory arguments have been advanced to support such a contention.

The more favourable treatment of the administrative group as compared with that of the professional group has occasionally been defended on the assumption that as it is the former group that sanctions the expenditure voted by the legislature, a wrong decision on its part would involve waste and a loss of public money. This argument, however, assumes that the decisions of the administrative group are always sound and correct, and it entirely overlooks the fact that when decisions affect the sanctioning of expenditure on technical projects, the question as to whether such expenditure will be prudent and profitable, or extravagant and wasteful, will depend wholly on the skill with which the technical details have been worked out, the ability of the technical officers who supervise its execution; and on the care in relation to administrative details exercised by them Therefore, even in the event of a consistent absence of mistakes on the part of the administrative group, the actual avoidance of wasteful expenditure and of the unprofitable use of public money must, in the very nature of things, rest, so far as the preparation and execution of technical projects are concerned, directly on the skill, scientific knowledge, and technical experience of the professional group, that is to say, on factors which he wholly and exclusively in the sphere of responsibility of this group.

The contention has also been advanced in the past that owing to the great diversity of the duties which fall on the professional group of the Civil Service, and the fact that it is made up of not less than a hundred grades, it is not possible to devise a suitable classification scheme for this group. This plea has, however, lost much of its force now that an Act has been passed in the United States providing for the classification of civilian positions within the district of Colombia and in the field services (American Classification Act of 1923—Public—No. 516-67th Congress: H.R. 8928). Under this statute the 'compensation schedules,' that is, salary scales, are grouped under five 'services,' namely, (1) the professional and scientific service; (2) the sub-pro-

fessional service; (3) the clerical, administrative, and fiscal service: (4) the custodial service: and (5) the clerical-mechanical service. The numbers of grades in the several 'services' naturally vary. but a distinctive feature of the Act is that in the case of the two most important groups, namely, the professional and scientific service and the clerical. administrative, and fiscal service, the salaries of the topmost grades in each of them are identical, and in each of these 'services' certain grades, it is recognised, represent positions of equivalent responsibility, which is in each case clearly set out, and they accordingly carry salary scales with identical minima and maxima. It should further be noted that in this Act the professional and scientific service occupies the position of paramount importance.

The present-day methods of conducting the work in government departments are also, in some cases, open to grave criticism, they are productive of unnecessary duplication of effort, and consequently uneconomical In practice, the reports of the heads of the professional and technical groups are addressed to the permanent head of the department, who, however, has frequently so heavy a burden to carry that he cannot personally deal with them, and the reports therefore pass into the hands of officers of various grades in his branch. The result is, as often as not, that attempts are made by clerical and administrative officers to criticise technical details. and a lengthy and wholly unnecessary correspondence, in consequence, ensues. In those departments in which the technical work is highly complex, and the magnitude of the operations carried on in relation thereto considerable, the whole of the duplication of effort referred to would be obviated if the burden of responsibility for the details of the technical work were definitely and unequivocally placed on the shoulders of the department's chief technical adviser. In certain cases the situation could, with advantage to the public service, be met by giving the administrative chief and the chief technical adviser a co-equal status, so that, whilst carrying out their respective duties in the closest collaboration, they should at the same time be held directly responsible to the Minister each for the work within his own sphere, instead of the latter being called upon, as is at present the somewhat illogical practice, to tender his advice to the Minister through the former.

If the unequal treatment of the administrative and professional groups in the Civil Service were merely a question of a certain class of officers being dissatisfied with its status, prospects, and remuneration, the subject could be dismissed without further comment. However, the matter is one which is far more serious. Under the present organisation in the Civil Service, and the system of conducting business in government departments, it is at times impossible, much to the detriment of the public service, for the professional men to exercise effective control over professional work, no matter how expert they may be in the technique of their profession; further, a considerable waste of energy on their part is also often involved. hence the urgent need for a thorough reform in matters affecting the status of the technical expert in the Civil Service.

#### The Secrets of the Beauty Parlour.

Handbuch der gesamten Parfumerie und Kosmetik: eine wissenschaftlich-praktische Darstellung der modernen Parfumerie einschliesslich der Herstellung der Toiletteseifen nebst einem Abriss der angewandten Kosmetik. Von Dr. Fred Winter. Pp. x+947. (Wien: Julius Springer, 1927.) 69 gold marks

WHEN Hotspur quarrelled with Henry IV. he excused himself on the ground that the King's Messenger "was perfumed like a milliner, and 'twixt his finger and his thumb he held a pouncet box, which ever and anon he gave his nose and took't away again" On the other hand, readers of "Romola" will remember that whenever Tito Melema did an unusually scurvy trick, his inventor left him in the hands of his learned friend Nello the barber, to be shaved, bathed, and perfumed, presumably in the hope that these processes might do something towards his moral regeneration.

It would be unreasonable to suggest that Hotspur and George Eliot respectively represent the attitude of men and women towards the use of cosmetics and perfumes, but it is a curious fact that while men have been known to carry their antipathy to odoriferous fluids so far as to postpone a necessary visit to the barber merely to avoid them, the majority of women like these things, buy them, and sometimes use them so lavishly as to be a source of discomfort to their neighbours.

The present-day demand for these glittering wares is enormous; their illustrated slogans occupy but do not always decorate, or should we say in the modern art slang add *décor* to, the hoardings everywhere, the flapper and her too evident toilet accessories are the unfailing standby of the journalist hard up for 'copy,' and the advent of a new artist in perfumery secures much free publicity in the

press, especially in those quaint corners which editors still dedicate to 'ladies,' but which few intelligent women will admit reading. All this gives the trade in cosmetics and perfumes what Sir Lawrence Weaver might call a "smell of Babbitt," but it should be remembered that such modern necessities as soap, dentifrice, and medicinal preparations are none the worse, when their natural odour or flavour is covered, and that in this and other equally unobjectionable but less easily defined directions there is a large legitimate field for the exercise of the perfumer's art. It is primarily with such ends in view that Dr. Winter has approached his subject and compiled this book.

Nearly 300 pages are devoted to discussion of the great variety of raw materials used in the industry, and thanks mainly to copious use of constitutional formulæ for the components of essential oils, an enormous amount of information has been compressed into this space. Perusal of this section leaves the reader with the kind of feeling, which must be experienced by an intelligent artisan who has just completed a conducted tour of a contmental picture gallery—a little bewildered, but satisfied that he has had all the starred pieces pointed out to him. So breathless is the pace that towards the end the guide has only time to ejaculate such things as—benzyl propionate, smells of jasmin with a suggestion of fruit—and to sketch the It would be remarkable if the guide did not stumble occasionally, and on p. 63 he appears to confuse myristic with myristicinic acid, though it is clear elsewhere that he knows the difference between the two. Scattered through this section are practical hints, which have an academic interest for the chemist, such as the statement that mixtures of vanillin and anthranilic esters are liable to stam the skin yellow, an involuntary testimonial to the reactivity of aldehydes, and the note on p. 212 that alloxan when applied to the skin produces a pink tint, due to the traces of ammonia present in perspiration, whence it appears that the blush of the modern maiden may originate in at least two ways, physiological or chemical, the latter being due to this ingenious application of the murexide reaction. A short summary of the fermentation theory occupies less than a page, and is an excellent sample of Dr. Winter's skill in compression and his conscientious desire to leave no part of his subject untouched.

In the next section the author 'gets down' to practical perfumery and discourses on the form of cosmetic materials—distillates, creams, balsams, jellies, pastes, powders, emulsions, etc.—with

No. 3032, Vol. 1201

abundant descriptions and illustrations of machinery for producing these things and pages of formulæ for the delectation of the practitioner Nor is the theoretical side neglected, for there are chapters on such fasemating subjects as the harmony of perfumes, the reaction mechanism of vapour waves, the mechanism of the mutual transformatory reactions of perfume materials, and the influence of the method of mixing on the tonality of the mixture. Writers on this subject have a habit of diverging into musical terms such as notes, tones, and harmony when mere science fails them in terminology These chapters are quite interesting, as samples of that subtle differentiation which we all find useful from time to time, though some of us are inclined to scoff at the Teutonic temperament which alone seems capable of producing it. Dr. Winter also provides a full description of modern toilet soap manufacture, written on the lines just described and including quite useful chapters on the cleansing and lathering properties of different kinds of soap. which may be commended to those who desire to find a reason for the faith that is in them regarding some particular brand of shaving soap.

The last section deals with practical cosmetics, a subject about the present position of which Dr. Winter is not altogether happy, judging from his introductory remarks on quacks and their frequent occupation of a field which belongs to the physician His discussion of the pharmacological action of some of the ingredients of cosmetics lends point to that suggestion, and, as he remarks, there is considerable danger in the indiscriminate use of such things as "eau mystérieuse," a perfumed solution of antipyrine, which on application to the skin deposits after a time a coherent coat of white powder; to theatrical artistes who must produce such effects he recommends instead a solution of phosphotungstic or phosphomolybdic acid The section is full of curious information of this kind, and is at least a remarkable tribute to the assiduity with which specialists in the art of cosmetics have ransacked scientific knowledge, and the ingenuity with which they have applied, or perhaps misapplied, it

A question asked in the House of Commons recently as to the possible dangers of the indiscriminate use of cosmetics seems to indicate that there are people who take a hygienic interest in these things. To them, as well as to those professionally interested, Dr. Winter's book may be cordially recommended as a source of accurate and recondite information, and beauty parlour specialists who can read German will find the volume a profitable investment T. A. H.

#### Social Classes and Social Welfare.

Social Differentiation By Prof. Cecil Clare North. (The University of North Carolina Social Study Series.) Pp. x +343 (Chapel Hill. N.C. University of North Carolina Press; London Oxford University Press, 1926.) 11s. 6d net.

RECENT visitor to America whose object was to see something of the teaching of the social sciences in that country was advised on landing not to omit the University of North Carolina. How long, his informant added the not conspicuously enlightened citizens of that State will tolerate the vigour and freedom of thought, especially in the dangerous region of social problems, now being displayed in their University, may be doubted. In any event, the study of the social sciences flourishes there at present. Sociologists are learning to regard The Journal of Social Forces as one of the best periodicals of its kind in any language, and to welcome additions to the series of studies to which the volume here reviewed belongs.

Prof North has made a sane and careful exammation of a problem of the first importance. His treatment is scientific. Unlike nine-tenths of those who deal with this subject, he is not the victim of any theory. The book cannot be called exciting; we have had, however, our full measure of exciting but superficial theories in sociology, especially from Europe. On the other hand, it is not ponderous, nor does it remind the reader of wading through wool, as do some of the contributions of his compatriots. What, he asks, are social differences? Why do they arise? And what is their relation to social welfare?

To the first question Prof. North replies that social differences may be divided into those of function, rank, culture and interest. Of these, those due to differences in rank are the most important. They include differences in respect to rights, privileges, or esteem, which may be personal, political, economic, religious, or honorific. These differences are the foundation of 'classes' in the strict sense, and when membership of a class is hereditary, we may speak of castes. It is perhaps a matter of doubt whether we should agree in regarding differences of interest as a separate form of social differentiation. It seems possible to resolve most of the examples here given of difference in interest into differences of function, rank, or culture. However that may be, there is clearly a close correlation between these various forms of social differentiation. A man's function will tend to carry with it a certain rank and a certain culture.

Prof North divides the factors which bring about social differences into the social and the biological. To the latter he gives full weight He thinks that slight but definite differences in intelligence exist between the average representatives of those performing various functions, and that considerable inherited differences exist between the true functioning groups on one hand and the pauper, thriftless, and criminal groups on the other. In this opinion he is probably justified. It may be remarked that this factor is becoming of greater importance. Modern society is elaborating a mechanism in the form of the educational ladder and vocational guidance whereby the young are being sifted and allocated to the functions they are most fitted to fulfil. Those engaged upon the improvement of this mechanism are wont to have us believe that there lies the path to social salvation. Everyone will be happy in his job and no one will envy anyone else, because it will be realised that those performing any given function are the best fitted for the job. This rosy picture is apt to be marred by the reflection that the capacities of the members of society may not be fitted to the functions. There may not be enough people, for example, innately suited to the routine which industry demands Account also has to be taken of the fact that inclination by no means always corresponds to capacity. All those who think themselves fitted to rule are not qualified to do so

Quite apart from these reflections, however, it may be seriously questioned whether, at least so long as rank differences persist, this biological sifting of the population is not likely to result in a dangerous segregation of the gifted members, dangerous to them and to those from whom they are separated, because there is sufficient common ground of humanity to make contact desirable, and dangerous to society because of the possible loss of the gifted through revolution or differential fertility.

Whatever may be the causes of social differentiation, its existence is of the utmost importance. Certain forms of social differentiation, chiefly those of rank, may bring unrest and sometimes revolution. For differences of rank there is little favourable to be said. On the other hand, without differences in function and culture, there is the danger of stagnation if not of decay. Functional differences may nevertheless result in unhealthy specialisation, as is the case with regard to the divorce between work by brain and work by hand to-day. The profoundly interesting study recently published by Rostovtzeff of the social and economic conditions in the Roman Empire seems to point to

the conclusion that the decay of that civilisation was due to the failure to compose differences that Prof North would call differences of rank. these led in the third century to convulsions to which an end was put by the fatal policy of the fourth century which enforced too great a uniformity.

Difficulties arising from differences of rank trouble modern society. The Russian solution seems to take the form of enforcing a uniformity which may be worse than the disease. There is no more urgent task than an examination of social differentiation in modern communities, with the object of ascertaining what differences are desirable and stimulating and what differences merely cause friction if nothing worse. Only when we have a clearer view than we possess at present of the functioning of society can we hope to apply rational control and so hope to pass beyond our present troubles.

A. M. C.-S.

### Electrons, Atoms, and Molecules.

Handbuch der Physik Herausgegeben von H.
Geiger und Karl Scheel. Band 22: Elektronen,
Atome, Molekule. Redigiert von H Geiger.
Pp. viii + 568 (Berlin Julius Springer, 1926.)
42 gold marks.

THIS twenty-second volume of the "Handbuch der Physik" is divided into six chapters dealing respectively with electrons, atomic nuclei. radioactivity, the ions in gases, size and structure of molecules, and the natural system of the chemical elements. The treatment is exceedingly clear and complete, and the twelve contributors deserve high praise both for the excellence of the subject matter and for the successful way in which they have avoided overlapping The production of the book, too, leaves nothing to be desired, and is worthy of the high standard we have grown to expect from Julius Springer. The numerous diagrams are uniform and very clear, and apart from the usual' subdivisions of the chapters and sections of the book, a useful feature is the statement at the head of each page of the actual topic under discussion A brief subject-index is given at the end of the volume, and a useful table of physical constants is included.

W. Gerlach presents, in Chap. i., an authoritative account of the various methods which have been used for the determination of the charge and specific charge of the electron, the principles and theory of each method being very clearly stated. The various results are critically discussed and the most probable values given. In his discussion of Ehren-

haft's work the author concludes that the evidence is opposed to the existence of the sub-electron

In Chap ii Kurt Philipp describes the theory and experimental verification of the scattering of a-rays in their passage through matter, as well as the scattering of \(\beta\)- and X-rays Determinations of the nuclear charge both by these methods and by the application of Moseley's law lead to the same results. This is followed by a brief account of the evaluation of the mass of atomic nuclei by the methods of J J. Thomson, Aston, and Dempster O Hahn describes the experimental work by virtue of which the identity of the a-particle with the helium nucleus was established, and Lise Meitner shows how we may gain information on nuclear structure from a study of Geiger and Nuttall's law, from the regularities observed in the emission of radiations by successive radioelements, and from the considera-The chapter closes tion of  $\beta$ - and  $\gamma$ -ray spectra with an illuminating account by Kirsch and Pettersson of work on atomic disruption by bombardment with a-particles.

The chapter on radioactivity, though brief. contains a valuable summary of the subject in its many aspects. In the section on radioactive disintegration. W Bothe describes the general theory of disintegration and the most important cases of successive change which arise in practice. We are then introduced to the work on the experimental verification of the theory, with special reference to fluctuations, and this is followed by an outline of the principal methods used in determining the main constants of radioactive change On pp 143 and 218, perhaps too much stress has been laid on the calculated heat production due to radium and its products, for although the aggregate value approximately agrees with experiment, the constituent values differ appreciably from the recent experimental determinations by Gurney and by Ellis and Wooster respectively of the values to be attributed to the B- and 7-rays

The various methods in use for detecting and measuring the activities of radioactive substances are admirably summarised by Stefan Meyer, who also deals with the preparation and main properties of each of the products in the three disintegration series, and gives a useful summary in tabular form of the constants of the radioelements. The application of the radioelements as indicators has been found of great service in a variety of chemical and physico-chemical investigations, and the results are ably summarised by O. Hahn, who also deals with the significance of radioactivity in the elucidation of problems connected with earth history. The

calculation of the influence of radioactive heat on the cooling of the earth, given on p 295, is due to Holmes, however, and not to Ingersoll and Zobel. Work on the thermal effect of potassium appeared too late to be included on p 292, and we believe that the unsuitability of thorium minerals for age determinations (p. 302) is more satisfactorily explained on the basis of a recent paper by Holmes (Phil May, vol 1 p. 1066: 1926) than by the proposal put forward in 1917 by Lawson

Chap iv contains a most valuable account of the ions in gases by Karl Przibram. After a historical introduction, an account is given of the main properties of an ionised gas, together with their theoretical interpretation. Next follows a very clear description of the different experimental methods and underlying theory for the determination of ionic mobilities, and of the influence of various factors such as pressure, temperature, and strength of field The ionic mobility in gaseous mixtures is also discussed, and reference made to the abnormally high and low mobilities obtained A section is devoted to under certain conditions the diffusion, recombination, and adsorption of ions, and the discussion of the kinetic theory of ionic constants is particularly welcome, for there are still many discrepancies between theory and experiment. Finally, after dealing with the charge, radius, and mass of ions, the chapter concludes with an account of the ionic wind, and the condensation of vapours on ions.

Karl F. Herzfeld is to be congratulated on his eminently readable and full treatment of the size and structure of molecules in Chap. v. In little more than one hundred pages the divers data are skilfully woven into a consistent scheme, and an interesting introduction is followed successively by an account of the methods used, and their results, of the position of the atomic nuclei in the molecule. and of the evidence on the structure of the electron The last two sections of this chapter are by H. G. Grimm, and deal lucidly with molecular volumes, the size of ions and its relation to ordinal number, and with atomic volumes and dimensions. To have collected together successfully material of such variety must have been no easy task, and little of importance appears to have been overlooked. Attention may perhaps be directed to the fact that in the section on thm films only one of Adam's numerous papers in the Proceedings of the Royal Society is quoted.

The concluding chapter in the book is a useful and well-written statement of our knowledge on the natural system of the chemical elements, by Fritz

Paneth. He deals in turn with periodic and nonperiodic properties, isotopy and the separation of isotopes, the distribution of the elements and atomic types in Nature, natural and artificial disintegration of the elements, and finally, with the interpretation of the experimental results from the viewpoint of the Rutherford-Bohr model of the atom.

#### Our Bookshelf.

Teaching Agricultural Vocations: a Manual for Teachers in Preparation and in Service By Prof. Rolland Maclaren Stewart and Arthur Kendall Getman Pp vii+377. (New York: John Wiley and Sons, Inc. London. Chapman and Hall Ltd., 1927.) 15s net.

This American manual well indicates the change that has taken place in the point of view of agricultural educationists in the United States. It has arisen since the passing by Congress of the Agricultural Extension Act of 1914, and the Federal Vocational Education Act of 1917, and is a wide departure from the old strictly professional and pedagogic view of adjusting and co-ordinating science and practice in agriculture.

science and practice in agriculture.

The aim of vocational education in agriculture has been well stated in these words: "It is the purpose of courses in Vocational Agriculture to aid in developing a type of American farmer who shall possess managerial ability and business capacity, an aptitude for farming and the necessary technical knowledge and skill to produce and market his products, and also one who is capable of adapting himself to our constantly changing social and economic life."

Vocational education in agriculture is a young movement, and the manual before us, intended "for teachers in preparation and in service," indicates this by the amount of propaganda it contains, especially the first six chapters, intended no doubt for "teachers in preparation." That the movement has gained ground rapidly in the United States is indicated by the Reports of the Federal Board for Vocational Education in Agriculture, which shows that the 15,453 pupils in 1918 had increased in 1926 to 108,862, a gain of more than 600 per cent. It is, therefore, not surprising with such an increase that text-books and manuals are

being published in increasing numbers

This manual is a step forward in the right direction. It takes a wide, perhaps discursive, outlook, but it is free from cut-and-dry formulæ. It covers the four types of vocational agricultural instruction as given in all-day schools, short-unit course schools, part-time schools, and evening schools. Each chapter is closed with an annotated bibliography, which is a good feature, but the index requires amplification to make it serviceable as a manual. There is one point to which exception must be taken. The responsibilities or duties of a teacher of vocational agriculture, as enumerated at pages 6-8, call for an agricultural 'Pooh-Bah.' No doubt time and experience will correct this.

To the English reader this manual will be of service for the insight it gives to the new movement in agricultural education in the United States

R Hedger Wallace

The Chemical Elements and their Compounds · an Introduction to the Study of Inorganic Chemistry from Modern Standpoints By Dr. J. A. V. Butler. Pp. xi+205. (London · Macmillan and Co. Ltd., 1927.) 68

The merits of a book on atomic and molecular structure can be judged by a very simple test. If the book merely gives an account of the personal views and impressions of the author, in the form of a long essay on valency, its value is probably not very great. but if it is written with a full sense of historic values, and is based at every point on the study of the original sources, the narrative immediately becomes of permanent value as a guide to the serious student of science

It is, therefore, a pleasure to find that Di. Butler has shown no desire to 'push' his own views on valency, but, on the contrary, has made a very successful effort to show precisely what was done by Dalton, Davy, Berzelius, Faraday, Frankland, Arrhenius, Werner, Thomson, Rutherford, Bohr, and the Braggs. In many cases he has cited the exact words of the author, and in a still larger number of cases he has shown in a diagram the apparatus that was used in those crucial tests which will be regarded in the future as 'classics' of experimental research.

As a result, the reader is able to follow step by step the logical stages by which modern theories have been suggested, tested, and established. This careful reproduction of original material has the further merit of making the book useful not only to the elementary student, who may be receiving a first introduction to theories of atomic and molecular structure, but also to many advanced students, whose second-hand knowledge of the subject may be too sketchy to be adequate

In addition to ten chapters of text and an epilogue, the book contains two appendices, the first dealing with "The Structure of Crystals," whilst the second is in the form of a "Periodic Table of the Elements, showing Arrangement of Electrons in Crystals."

in Groups."

China: Land of Famine. By Walter H. Mallory. With a Foreword by Dr. John H. Finley. (American Geographical Society: Special Publication No. 6) Pp xvi+199 (New York: American Geographical Society, 1926.) 4 dollars.

THE greater part of China's millions exist—not live—on the starvation line. The grim spectre of famine stalks about the land. "Have you eaten?" is the common salutation. Yet, in spite of wars and pestilence, floods and droughts, the population continues to multiply, and the problem of the food-supply becomes more and more insistent. The struggle for mere existence has become indescribably hard. Little wonder, therefore, that national energy is being sapped and perception dulled, and

that a race at one time in the van of civilisation has become the prey of anarchy and misrule

The author, who was attached to the China International Relief Commission, discusses in temperate but telling language the economic, natural political, and social causes of the per-manent food shortage within the country, and suggests corresponding remedies. Relief measures, he admits, are merely temporary palliatives. It is for the millions themselves to take the initiative and seek the guidance of modern science in the solution of the pressing problems of their country This implies however, the education of the masses under a stable and enlightened government, a condition which at the moment seems impossible of attainment The book ends, therefore, on a mmor key with the warning that the unhappy fate of China should be carefully studied by the great nations of the west, whose remarkable progress is also in danger of becoming assailed by the dragon of over-population.

In Ashanti and Beyond By A. W. Cardinall Pp. 288+16 plates. (London: Seeley, Service and Co., Ltd., 1927.) 21s net

MR CARDINALL has written a pleasant, readable book, full of good spirits and tempered with good sense. The author has had many years' experience in tropical Africa as a resident magistrate, and he writes mainly of his first journey and impressions This method gives a clear picture of conditions which are changing rapidly, but the observations are necessarily superficial though accurate so far as they go The book can scarcely be regarded as a contribution to anthropology, although many items of interest concerning native life, customs, and behef are mentioned, and this is to be regretted, as the author seems always to have been on excellent terms with the natives. Quite unexpected is the account of the snail industry: for the gathering curing, and selling of snails for food by the forest peoples is so well organised as to be nothing less The author states that no estimate has ever been made of their trade value, but that it must be 'colossal'. a few years ago the local chiefs forbade snailcatching for three years, for fear of complete destruction of the stock. Perhaps the most interesting part of the book is the description of the Great North Road from Kumasie which leads to "Timbucktu, the desert and to the unknown mysteries of Africa "On the whole, one learns that, in spite of flies. "the land of death" is a cheery place for a sojourn so long as there is just enough work to do.

Running, Maintenance and Repair of Diesel Engines. By Philip H. Smith. Pp. 159 (London: Constable and Co., Ltd., 1927) 3s. 6d net.

A VERY practical treatise intended for those entrusted with the operation of Diesel engine plants, particularly land installations. The first two chapters are really hors-d'œuvre, dealing briefly with the selection of the type most suitable to requirements, and with the rehability of Diesel

engines relatively to other prime movers. The index of reliability is determined from insurance claims, but the value of the conclusions arrived at cannot be assessed as the statistics are not given. It is not clear whether extent or number of claims is taken as the criterion

The real business of the book commences in the succeeding chapters, which take a comprehensive survey of the defects hable to develop during the operation of the plant. Each part of the engine is separately dealt with and its usual and possible ways of failing on service are discussed. In each case the symptoms and the probable effect of the defect as well as the measures to be taken for avoiding and for rectifying it are fully described, and in those cases where the initial cause in not obvious, a thoughtful investigation is made into the probable origin of the trouble Brief but useful notes are also given on the maintenance of proper running conditions, on indicator diagrams, and on valve setting For its size the book contains a lot of useful information Evidently the author has had a wide experience of Diesel engine operation, and the reader is given full opportunity to benefit from this valuable experience.

Abridged Callendar Steam Tables: Fahrenheit Units By Prof H. L. Callendar Second edition Pp. 8 (London: Edward Arnold and Co, 1927) 1s net

The tables are in a very useful form for the practical engineer. The properties of saturated steam are given for absolute pressures from 0.5 lb. to 500 lb. per square inch, at well-chosen intervals which do not amount to corresponding temperature differences of more than 2° to 3° F

For dry steam (superheated and supersaturated) the total heat and entropy are given, in separate tables, at absolute pressures from 15 lb. to 500 lb per square inch, the intervals corresponding to saturation temperature differences of 14° to  $22^{\circ}$  F , and superheats from  $-60^{\circ}$  to  $-400^{\circ}$  F., at intervals of  $20^{\circ}$  F. up to  $200^{\circ}$  F, and thereafter of  $40^{\circ}$  F.

A useful list of equations is given in a form convenient for reference. The tables are also published in centigrade units.

L. M. D.

Vorlesungen uber Thermodynamik. Von Prof. Dr. Max Planck. Achte Auflage. Pp. x+287. (Berlin und Leipzig: Walter de Gruyter und Co, 1927.)

Although Prof. Planck's "Thermodynamics" first appeared thirty years ago, it remains still one of the clearest books on the subject at the present day. The eighth edition has 17 sections and about 40 pages more than the first, but the sections up to 280 are numbered as before. The additional sections deal with Nernst's theorem and its consequences T is now used for the absolute temperature instead of  $\zeta$ , certain proofs formerly based on the properties of a perfect gas have been made general, and the treatment of electrolytes has been improved. The new edition is well printed, but the paper of it compares unfavourably with that of the first edition.

#### The Radioactivity of Potassium.

THE work of Aston has shown that potassium, which has an atomic weight of 39 104 (Honigschmid), is a mixture of two isotopes. The atomic masses of these are 39 and 41, and they are present in ordinary potassium in the proportion of 20 to 1 respectively. Potassium emits a fairly penetrating 3-radiation, and we are led to inquire as to which of the isotopes is responsible for the emission of  $\beta$ -rays. It may be that there is a third isotope present in potassium, but in such small amounts that its detection by the mass spectograph is impracticable. Such a possibility has been discussed by Harkins (Proc. Nat. Acad. Sci., vol. 11, p. 630; 1925), who considers that isotopes of mass  $4\bar{0}$  or 41, the former of which is unknown, are the ones most likely to be radioactive. Harkins considers the hypothetical isotope of mass 43 (Kossel: Phys. Zert., vol. 20; 1919) to be less probable.

We can arrive at a solution of the problem by carrying out a partial separation of the isotopes of potassium and examining the activities of the frac-tions obtained. By way of illustration we may suppose that such a partial separation leads to a concentration of the isotope 41, and that the atomic weight of the 'heavy' fraction is found to be 0 005 unit greater than that of ordinary potassium. The obvious conclusion from such a result would be that whereas ordinary potassium contains 520 per cent. of potassium 41, the 'heavy' fraction contains 545 per cent. of that isotope. If the radioactivity of potassium is to be ascribed to the isotope of mass 41, we should then expect to find that the activity of the 'heavy' fraction would be 48 per cent. greater than that of ordinary potassium. Should the activity be due to a hypothetical isotope of mass 43, the difference in activity would be  $\sqrt{2} \times 4.8$  per cent. On the other hand, if the activity be attributable to the chief isotope of mass 39, we should find that the heavy fraction would be 0.2 per cent. less active than ordinary potassium.

Shortly after they were successful in effecting a partial separation of the isotopes of mercury and of chlorine, by the method of ideal distillation, Brønsted and the present writer undertook an elaborate research on the separation of the isotopes of potassium. After several unsuccessful attempts the work was discontinued, as we were engaged on other more pressing problems. It was taken up again later by one of us (G. H.) in collaboration with Miss Løgstrup.

About one litre of molten potassium was introduced into the first of a system of Pyrex bulbs connected to a high vacuum. By means of an electric heater and an asbestos cylinder containing carbon dioxide snow the potassium could be distilled from the lower to the upper half of the bulb, and in this way repeated distillations were carried out, the apparatus being maintained at a high vacuum all the time. The later operations of ideal distillation were performed in the succeeding bulbs, the carefully purified liquid potassium being heated to about 160° C. and the cooled potassium surface on which condensation was to take place being cooled by solid carbon dioxide. It was arranged that the distance between the bot and cold surfaces was maintained at less than

1 cm. After each operation of ideal distillation about 1-2 cc of potassium residue remained, and this was transferred (in vacuo) to the next bulb. This operation was repeated ten times, and the whole of the residual heavy fractions were collected together so as to have ample material for an atomic weight determination. Full details of the distillation

process will be published elsewhere

Prof. Honigschmid kindly undertook to determine the atomic weight of the residual heavy potassium fraction, and for this he found an atomic weight 0 005  $(\pm 1)$  unit in excess of that of ordinary potassium. It was now necessary to compare the activity of the heavy fraction with that of ordinary potassium Owing to the feeble radioactivity of potassium great difficulty was experienced in obtaining a sufficiently high insulation of the  $\beta$ -ray electroscope to ensure an exact comparison of the two activities, and ultimately it was decided to abandon this method in favour of the Hoffmann vacuum electrometer. Through the courtesy of Prof G Hoffmann the measurements were carried out in his laboratory at Konigsberg The difference between the activities of the heavy potassium fraction and ordinary potassium was found to be  $4.2\pm0.7$  per cent. In each case the material was converted into potassium chloride for the purpose of measurement. This result is in good agreement with that to be expected from the observed change in atomic weight, on the assumption that the activity of potassium is due to the isotope of mass 41. We are thus led to the conclusion that the potassium isotope 41 is mainly if not solely responsible for the observed radioactivity of potassium.

If we make the assumption that in the case of rubidium the activity is also due to the heavier of the two isotopes 85 and 87, we get a simple general explanation of the greater intensity of the activity of rubidium as compared with potassium. The heavier isotope is four times more strongly represented in rubidium than in potassium, and hence the tota activity of rubidium is approximately four times that of potassium. On the other hand, cassium is a pure element, and the absence of radioactivity in the case of this element can readily be explained by similar reasoning, as suggested by Aston some time ago (Ann. Rep. Chem. Soc., vol. 21, p. 258; 1924)

According to Holmes and Lawson (NATURE, vol. 117, p. 620; 1926) the most probable half-value period of potassium is  $T_{\rm K}=1~5\times10^{12}$  years. This value was obtained on the basis of very careful and detailed considerations of the relative  $\beta$ -ray activities of potassium, rubidium, and uranium, and by assuming that both the isotopes 39 and 41, 1e. the whole of ordinary potassium, are radioactive. Should the radioactivity be confined to the 41 constituent of the mixed element, it was shown that the half-value period of the isotope of mass 41 would be  $7.5 \times 10^{10}$ years (Holmes and Lawson: Phil. Mag., vol. ii. p. 1224; 1926). Now it has been shown above that the radioactivity of potassium is to be ascribed to the isotope 41, so that the latter figure for the halfperiod is the true one. Radioactive measurements give no indication of the period of the common potassium isotope of mass 39, and this does not appear to differ from other stable elements in respect of its radioactivity.

The above conclusions in no way affect the interesting results obtained by Holmes and Lawson (Phil. Mag., l.c.) on the radioactivity of potassium and its geological significance. From the calculated period of potassium 41 it follows that since the consolidation of the earth's crust about 2 per cent. of this isotope will have disintegrated, and we are led to the conclusion that at that early stage of the earth's history

the atomic weight of potassium would be 0.002 of a unit higher than it is to-day. Should they lack other methods, chemists of the very distant future will be able, by redetermining its atomic weight, to calculate the lapse of time since the first modern atomic

weight determination of potassium.

If we assume that the emission of 3-particles effects an alteration in the nuclear charge, the product of transformation of potassium will be a calcium isotope of atomic weight 41. We have seen that since the consolidation of the earth's crust about 2 per cent. of potassium of mass 41 will have decayed, so that the maximum amount of calcium 41 which has accumulated in potassium minerals during the whole of geological time will amount to only 0.1 per cent. of their potassium content. This should be capable of detection in determinations of the atomic weight of calcium which has been extracted from old potassium minerals.

#### Theory of the Upper Atmosphere and Meteors.

IT has been clearly recognised that the force of gravity acting on the atmosphere of the earth will cause the heavier gases to settle downward by diffusion and the lighter gases to rise to the higher altitude, and that winds, if they exist, would by convection keep the composition of the air uniform at all elevations. The classical ideas of atmospheric pressures (for example, Humphreys, Jeans, Chapman, and Milne, etc ) have been based on the assumption that convection is negligible, at least above a 50 km level, and that diffusion is the important factor in determining the partial pressures of the gases. In this note are presented some conclusions, to be published in detail later, which have resulted from taking into account convection and diurnal temperature variations in the high atmosphere.

The ordinary equations of diffusion show at once that if the air were uniformly mixed at all altitudes and then left free from all convection currents, there would be a constant flow of lighter molecules upward and of heavier molecules downward, which would be independent of the altitude until a level was reached where the diffusing gas would be in gravity equilibrium. This 'diffusion' level for hydrogen would move from infinity down to 142 km. in one day, at the end of five days it would be at a height of 127 km., and in 50 days it would be at 113 km. The corresponding levels for helium would be at 137, 120, and 106 km respectively. The new calculations give hydrogen and helium contents above 150 km roughly 1/100,000 of

the values previously calculated.

Absorption of solar and terrestrial radiation must be taken into account in any discussion of radiation equilibrium in the upper atmosphere. Numerous writers have recognised this fact, but apparently none of them has made an attempt to calculate absorption coefficients or to estimate a difference of temperature for day and night, or winter and summer conditions. Water vapour above II km. absorbs a little more than 20 per cent. of black body radiation from below at earth temperatures, while carbon dioxide absorbs nearly 40 per cent. Ozone absorbs only about 2 per cent., but its presence is important because it absorbs about 4 per cent. of the solar radiation at an altitude where most of the re-radiation must be by the ozone itself. Temperature calculations based on these absorption coefficients show that for a 50° latitude above a height of 60 km. we should expect a temperature of about 250° K. during a winter day with a drop to 220° during the night, and a temperature of 370° during a summer day with a corresponding drop

to 230° during the night

The atmosphere at the base of the stratosphere cannot be in radiation equilibrium, but must receive more radiant energy than it loses both from above and below during a 24-hour day. The temperature condition of the earth's surface is in very unstable equilibrium. The loss in heat by radiation from the warm equator is much less than from the cooler polar regions. An increase in temperature at sea-level near the equator would not result in an increase in the energy lost by radiation from these regions, but would actually result in a decrease. Loss of heat by radiation from the earth depends not on the condition of the surface, but on the temperature at the base of the stratosphere and absorption in the stratosphere A slight change in the carbon dioxide of the air would have a tremendous influence on the climate of the earth. If the carbon dioxide content of the air were increased from the present 0 03 per cent to 0 I per cent., tropical plants would probably grow in the polar On the other hand, if this protecting sheet decreased from 003 per cent. to 001 per cent., ice would probably be found near the equator.

Since the present theory leads to low densities of the atmosphere above heights of 100 km. or so, densities much lower than those of classical tables, the facts about the appearances of meteors require explanation. It seems possible to do this following to a certam extent the ideas of Sparrow and departing from those of Lindemann. When a high-speed meteor strikes an air molecule, it is assumed that the energy of the impact violently ejects atoms, molecules, and possibly small particles of molecular dimensions from the body of the meteor This ejected material, by virtue of its velocity, carries into the air the energy which eventually gives the light of the meteor trail. For example, when a nitrogen molecule strikes an iron meteor which has a velocity of 40 km. per second, the energy of the impact is sufficient to raise the temperature of 1800 molecules 1000° C., or to evaporate 56 molecules of iron, or to evaporate and ionise 24 molecules of iron. As a result of this impact, a mass roughly thirty times that of the nitrogen molecule is ejected from the meteor principally in the form of highly energised iron atoms which have velocities slightly greater than that of the meteor itself. The melastic collisions of these iron atoms with the molecules of the air result in the visible trail

The excitation energy of these collisions may be as high as 155 volts for nitrogen or 280 volts for argon. Much of this energy may be radiated in the ultra-violet or even soft X-ray region, and it is probable that not more than one-tenth of the total radiation is in the visible part of the spectrum Therefore, the total mass of the meteor must be much more than that derived by Lindemann and Dobson from their considerations of the relation between the mass of a meteor and its light. The temperature changes in the upper atmosphere from evening to morning, and from winter to summer, given by the present theory, lead one to expect appearance of meteors at heights which are greater by, say, 5 km. in the evening than in the morning, and in the summer than in the winter. It would be interesting to know whether this difference has been observed.

#### Descent and Divergence.

IN Sir Arthur Keith's presidential address to the British Association at Leeds (Supplement to Nature, Sept 3, 1927), reteience is made to "the zigzag line of man's descent." It seemed desirable, if possible, to have some graphic method of crystallising, as in a nutshell, the views of the present moment as deduced from the results attained by leading investigators in this field. To that end the adjoining chart (Fig. 1)

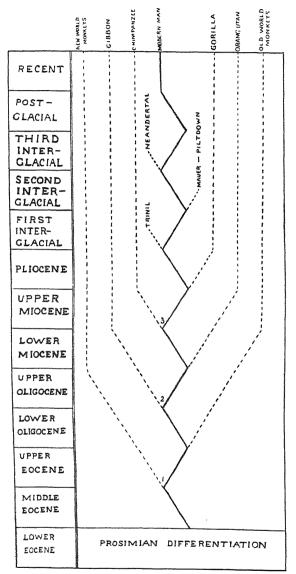

Fig. 1.

may be found useful, and a few words in justification

of it may be permitted.

In one of the best osteological diagrams ever devised, T. H. Huxley portrayed a procession of anthropoids as "a single file of skeletons" from gibbon to man. Needless to say, he did not intend to suggest a simple series of transformations such as a mere glance at the illustration might mislead one into supposing, but to demonstrate, like Pierre Belon's parallel figures of the skeletons of bird and man published in the middle of the sixteenth century, the

unity of plan of composition of these beings. Of course he knew that no zoological gradation of recent forms coincides with their geological succession. In the same mimitable essay ("Man's Place in Nature," 1863) there is a series of sections of the skulls of man and various apes "drawn so as to give the cerebral cavity the same length in each case, thereby displaying the varying proportions of the facial bones."

In the annexed chart the geological time-intervals are reduced to the same duration in order to bring out the corresponding evolutionary impulses which may be imagined to have stirred the nascent stocks to climatic fitness during those strenuous periods. Each stage advanced in a certain direction until what Prof. J. Arthur Thomson has aptly termed a strain-limit' was reached; the human way then became diverted to a new trend, while the simian strain continued along 'the lane that had no turning.' Some of the causes which were at work in effecting the first or platy-catarrhine divergence are sufficiently obvious, and it is interesting to find continental division joining forces with morphological divergence. The next parting of the ways, indicated on the chart, may be distinguished as the satyrine, and the third as the troglodyte divergence. These are milestones ın human descent.

The censure which such a speculative chart justly deserves would be instructive should the line it takes become known.

ARTHUR WILLEY.

McGill University, Montreal, Canada, Oct. 17.

#### Association in Liquids.

The following seems to be a possible means of investigating the question of association. Without going into the experimental and mechanical difficulties, which are great but not insuperable, I will indicate briefly the general idea, and for that purpose will take the simplest optical system of several that might be used.

Consider a liquid contained in a tubular cell which is closed at the top by a semi-platmised plate and by a mirror at the bottom; with proper adjustment we shall observe a system of interference rings centred about the vertical axis of the cell

Let the cell be mounted as a centrifuge and be fitted so that the speed of rotation, which is to be completely

controllable, is known.

It is clear that on rotation there will be a movement of the rings across the field of view. Assuming that both the number of rings and the rate at which they pass can be noted, we get a complete insight into the changes in the 'optical density' of the liquid.

Knowing the speed of rotation and the compressibility of the liquid, we can calculate its bulk density at

any point on the radius of the cell.

There are three cases to be considered.

(1) With a pure unassociated liquid we may take it that the calculated bulk density is reached practically instantaneously, so that even while the speed is changing it will coincide with the optical density.

(2) With a dilute solution the two densities will no longer coincide. The compressing effect will, as before, be instantaneous, but the difference between the two densities will, while the speed is changing, be dependent on the osmotic pressure and the rate of diffusion of the solute. Obviously the slower the rate of change of speed the less the discrepancy. When the steady state at any constant speed has been reached, the difference will be a measure of the concentration of the solute.

Thus it would seem that a solution can be distin-

guished from a pure liquid by seeing whether the rings continue to move after the constant speed is reached.

(3) With concentrated solutions, the effects are more complicated, but they need not concern us here

Now it is easy to show that an associated liquid is but a special case of miscible liquids, and as such is subject to all the osmotic laws. If we select a liquid which is but slightly associated it would come under category (2), and, on centrifuging, the two sets of molecules would, in general, be temporarily separated; and if we know from other sources their relative concentration, valuable light on the type of association might be obtained

It may be pointed out that the sensitiveness of the method is, among other things, proportional (approximately) to the depth of liquid under examination: thus using a long column and a suitable optical system it might be possible to separate isotopes which are not

otherwise separable.

As bearing on the whole subject I would direct attention to a paper by the late Dr. C. V. Burton and me on the "osmotic theory of solutions" (Phd. Mag., 1909.

ment between the term values (see Table I.) of certain band groups of the many lined spectrum of H<sub>2</sub> which he analysed (*Proc. Roy. Soc..* 113, 400, 1926) and the triplet system of the atomic helium spectrum. In the case of He<sub>2</sub> and H<sub>2</sub> the analogy can be carried further in detail, due to the fact that under the usual conditions of excitation the band groups of the triplet system of He<sub>2</sub> ('Main-series') and the corresponding groups in the many lined spectrum of hydrogen (Fulcher bands, etc.. see *Proc. Roy Soc..* 113, 368; 1926) appear in greater intensity than the band groups of the singlet system of He<sub>2</sub> ('Second series') and the corresponding groups of the many-lined spectrum of H<sub>2</sub>. Furthermore, there appear relatively many lines in the *Q*-branches of the band spectrum of He<sub>2</sub> and in the many-lined spectrum of H<sub>2</sub>, while the *P*- and *R*-branches fade out with comparatively low rotational quantum numbers.

Table I. gives a summary of the arrangement and magnitude of such of the electronic terms (in effective quantum numbers) of the spectra of He<sub>2</sub>, He, and H<sub>2</sub>

as have been analysed.

The existence of the well-known 23S state in the

p. 598; there are printer's errors on p. 612), which may help in the matter; indeed, the optical method indicated above was devised by us so as to continue the centrifuging experiments mentioned therem; but I am not in a position to pursue the research any further.

Since writing the above I have seen Messrs. Raman and Krishnan's letter on "The Maxwell Effect in Liquids" (NATURE, Nov. 19). It would be interesting to see whether the 'optical' centrifuge could be used to test their theory; if, however, it takes time for asymmetric molecules to orient themselves, it will be difficult to distinguish between this effect and that caused by association.

BERKELEY.

Berkeley Castle, Gloucestershire.

# Absorption Experiments on Excited Molecular Hydrogen.

RECENT investigations on the band spectrum of helium and the many-lined spectrum of hydrogen seem to show that there is a far-reaching analogy between the arrangement and location of the electronic states of the term systems of the spectra of He, He<sub>2</sub>, and H<sub>2</sub>. For the spectra of He and He<sub>2</sub> this analogy has been discussed by Mullikan (*Proc. Nat. Acad. Sci.*, 12, 158; 1925) and extended by the author (*Proc. Nat. Acad. Sci.*, 13, 213; 1927). In regard to the correspondence between the electronic states of He and H<sub>2</sub>, Richardson demonstrated a remarkable agree-

helium spectrum, and the fact that intercombinations between the triplet and singlet systems mentioned in Table I. have not been observed (except for the combination \ 591 56 found by Lyman in the helium spectrum, which he classifies as the transition  $1^1S_0 - 2^3P_1$ ) led ine to look for a corresponding metastable state of  $H_2$  by absorption experiments in excited molecular hydrogen. The experimental conditions in the emission tube were chosen so as to produce the many-lined spectrum in particular. In the absorption tube a weak electric excitation of the hydrogen gas was used in order to excite any existing metastable states, that these might be the initial states of absorption for the radiation of the  $H_2$ -molecules in the emission tube. If there is any absorption it should be shown by self-reversal of certain band lines.

The absorption measurements which have been made over the whole region of the visible many-lined spectrum seem, indeed, to have the expected result. A number of intense lines, which are not distributed over the whole spectrum but are located in definitely bounded regions, distinctly show self-reversal, while other intense lines scattered over the whole spectrum do not show any absorption. The study of the series relations of the reversed lines is in progress. After further experiments the results will be published elsewhere in detail. It is intended to extend the absorption experiments to excited molecular helium.

L. A. SOMMER.

Jefferson Physical Laboratory, Cambridge (Mass.), Sept. 30.

#### Oxide of Fluorine or Fluoride of Oxygen?

THE ISSUE OF NATURE OF Nov. 5, p 672, contains the news of a very important discovery made by Messrs. P Lebeau and A. Damiens and communicated to the Paris Academy of Sciences on Oct. 3 (see Comptes rendus, pp. 652-654, 1927). In the preparation of fluorine by the electrolysis of the acid potassium fluoride, it was noticed that at the commencement of the operation, owing to the presence in the liquid of a small quantity of water, a new gas was obtained of which the formula has been established as F<sub>2</sub>O, probably a monoxide of fluorine. In my view the new gas is not a monoxide of fluorine, F2O, but a difluoride of oxygen, OF2 The two formulæ are by no means identical, and it is interesting to note that a famous investigator like Prof. Lebeau has overlooked the true state of the matter, for he says that it is  $OF_2$  (i.e. our  $F_2O$ , but he places the negative element first!) "paraissant être plutôt un oxyde qu'un anhydride."

Having been brought up on the electrochemical theory of Berzelius, I always regarded the chemical elements from the point of view whether they are, more or less, electropositive or electronegative—a point of view which was not accepted by my great teacher Mendeléeff (see Ostwald's "Klassiker," No 68, p 60)—and I was much gratified when Arrhenius in his electrochemical theory appeared as a Berzelius redivivus.' As regards the second series of the Periodic System or Classification of Mendeléeff (it was formerly called 'Law' in England, but the denomination 'Table' seems to me to be inadequate for a brilliant, fundamental, theoretical idea!) this series begins with a strongly electropositive element, lithium, and ends with the most negative of all elements, fluorine, thus:

#### + Li Be B C N O F - (Ne).

All the first five elements form oxides in which they are positive and the oxygen negative, and even ozone may be regarded as an oxide of (+quadrivalent) oxygen. But it was pointed out by me alone, in my lectures more than thirty years ago, in my introduction to Mendeléeff's Periodic System, 1907, and in Abegg's "Handbuch," vol. iv. 2, p. 2 (with Auerbach, 1913), that fluorine cannot form oxides, hydroxides, or oxy-acids, because it is more negative than oxygen. At the utmost a fluoride of oxygen  $(O +) (F -)_x$  could exist. Indeed, this is the new gas discovered by Lebeau and Damiens . OF<sub>2</sub>, not F<sub>2</sub>O. The difference between the two formulæ is best seen on representing how the electrons pass from the positive to the negative atom :

The first formula is impossible, the second, third, and fourth are analogous. As the inner constitution of the difluoride of oxygen, OF<sub>2</sub> is different from that of the chlorine monoxide Cl<sub>2</sub>O, it is easily understood that their chemical and physical properties will not be analogous.

It may be that a trace of this gas, possessing a peculiar odour, different from hydrofluoric acid or fluorine, was formed when I treated the new double oxide Pb<sub>5</sub>O<sub>7</sub>. 3H<sub>2</sub>O with concentrated hydrofluoric acid (Manchester, 1881).

BOHUSLAV BRAUNER

Bohemian Academy, Prague, Nov. 8.

No. 3032, Vol. 1201

#### Winter Thunderstorms.

In January last an appeal was made for reports of any thunder or lightning which might be observed before April 1, 1927 (Nature, 119, Jan. 22, 1927, p. 123) The census of storms was carried out in conjunction with the Meteorological Office, and efforts were made to obtain the co-operation of observers in all parts of the British Islands. Considering the whole of the six months from October 1926 to March 1927, thunderstorms occurred somewhere in the British Isles on 96 days out of 182 Details for the individual months are given in the following Table:

	England	Wales	Scotland	Ireland	British Isles	
1926						
October .	16	11	10	9	21	
November .	18	11	10	12	20	Ì
December .	5	1	4	0	8	l
1927						ľ
January .	14	8	16	14	23	
February .	6	1	3	2	7	1
March .	14	5	3	7	17	1
						-
Total (six months)	73	37	46	44	96	

In England and Wales there were five prominent stormy areas, namely, Sussex and Surrey, Devon and Cornwall, the Severn valley, south-west Yorkshire and the Lake District. In Scotland and Ireland the central portions of the west coasts of each country were particularly disturbed. Similar features have been noticed in previous winters. A lane of no storms ran from Dorset to the Wash, and large portions of the northern English counties were also free from storms.

Considering the first three months only of each of the past five years, 1927, 1926, and 1924 were comparatively free from thunder, while 1925 was

particularly stormy

The investigation is being continued during the present winter, and I shall again be very grateful for reports of any thunder, lightning, or hail which may be observed by readers of NATURE before April 1, 1928. A note of the place, date, and time of the occurrence, with the direction in which the lightning was seen, especially at night, will be very valuable. Any additional information of the following character will, in the case of actual thunderstorms, be extremely welcome. (1) The time when the storm passed overhead, or was nearest, with its direction; how long it lasted; (2) severity of storm, much or little thunder or lightning; (3) whether accompanied by hail, rain, or snow; (4) direction and strength of wind; change of wind (if any); (5) whether there was a change in temperature during the storm. S. Morris Bower.

Langley Terrace, Oakes, Huddersfield, Nov. 19.

#### Science and Survival.

In an article on page 613 of NATURE for Oct 29, headed "Science and Survival," the reviewer of a book called "The Bridge" asks certain pertinent questions which deserve an answer. Unanswered, they may suggest to a student of the book erroneous hypotheses which will lead him astray. I appreciate the fairness of the review: my object is only to furnish the additional

information virtually asked for, in the interests of truth

First, then, as to the identity of "a man in Cardiff," who might be erroneously regarded as a concealed source of normal information. This unspecified gentleman, I now find, is willing to give his name in confidence to the editor and to the reviewer; who will thus see that he is a responsible person, and emphatically not the kind of man who would give information to mediums, or attempt to spoil an experiment. As a matter of tact, he was not aware of the experiment until it was over; he never saw or communicated with Mrs. White at all after it had been planned. He was a mere initial incident, and to bring him into the matter would be to follow a false scent.

Next concerning Damais Walker First, if she had not happened to be living with her sister, unoccupied at the time, and therefore with leisure to try to develop her psychical faculty, the experiment on which the case is based would not have been started Secondly, the information she gave was not, when she gave it, known to anyone in the house; nor was it readily ascertainable by inquiry. The music-room, for example, had not been decorated and arranged, as described, since Mrs. White had got into touch with Nea Walker. Thirdly, the descriptions given by Damaris Walker were not returned upon and amended afterwards; each record was complete and done with, before it was annotated by a survivor and so verified as correct.

The reviewer duly appreciates and directs attention to the difficulty involved in selection of incidents. I have had an opportunity of seeing the whole, and am able to assert strongly that no omission has been made in order to strengthen the case. Selection was necessary solely because of comparatively irrelevant or only distantly related matter, referring to "the group" and other people. It was difficult to determine how much to include and what to cut out. Advice of experts was taken, and the book thus kept within reasonable limits; but never was a weak point intentionally omitted.

OLIVER LODGE

Normanton House, Lake, Salisbury, Nov. 26.

#### The So-called Viscid Secretion in Spawning Oysters.

In literature dealing with the Flat or European oyster, O. edulis, the statement is frequently made that when the eggs are spawned into the mantle cavity they are held together there and fastened to the gills by a white viscid secretion There is no doubt that this statement is incorrect and that what has been described as a white viscid secretion is an extrusion of blood-cells entangled in mucus. In a fairly recent publication (Fish. Inv., 3, 1923: London, 1924) I have shown that when oysters are taken out of water—and especially when transported or retained out of water some time—in hot weather, an extensive diapedesis, or 'bleeding,' occurs Now a large proportion of white-Now a large proportion of whitesick oysters, even after lying on a bench some hours, in the breeding, that is, warm, season, begin to 'bleed' more or less, in relation to the temperature and time out of water; further, many oysters spawn at the instant of dredging or after being taken out of water, and in such cases heavier bleeding than usual is liable to occur. It is, however, possible that a certain amount of—but not necessarily extensive—bleeding does normally occur at the act of spawning.

The concurrence of bleeding at or after the spawning act has given rise to the view that the embryos are actually fastened to the gills. In the course of

recent work (Jour. M B.A, 4, 4; 1927) it was necessary to examine oysters, immediately after they were dredged, either on the foreshore or in sheds adjacent to the dredging boats. In a few cases individuals were found with eggs in a fertilised but unsegmented condition, that is, just spawned. In these critical cases there was no viscid secretion, nor was there any in these circumstances in a large percentage of cases where the embryos were white but in various stages of segmentation later than the 2-celled condition. Moreover, when a secretion of this kind is present, it generally occurs in isolated masses, and does not encompass the whole of the embryos.

The so-called viscid secretion is, therefore, a mass of blood cells entangled in mucus; it is formed when oysters are kept out of water in warm weather as a result of diapedesis. The blood cells are sloughed off the gill in mucus in variable quantities, sometimes in great numbers, and a variable number of embryos may also become entangled in the mucus, but the number of embryos so entangled is usually relatively very few. The cause of diapedesis in oysters is no doubt capable of an exact physical expression, which, however, still remains to be found.

## An Unrecorded Constituent of Commercial Ethyl Ether.

For anæsthetic purposes a pure diethyl ether is now generally recognised as a desideratum. An opportunity recently arose for carrying out some experiments on the bromine absorption of commercial anæsthetic ethers, a standard solution of bromine in glacial acetic acid being added, and light excluded to avoid direct substitution of the ether by bromine. The products from six manufacturers absorbed bromine to different extents, as is shown by the following figures .—A, 06, B, 25; C, 7.5; D, 116; E, 136; F, 15 9. These are the numbers of c.c. of deci-normal bromine absorbed by 100 c.c. of the different ethers in the dark in one hour, which in the absence of aldehydes give a measure of the degree of unsaturation of the ethers On examination of the bromination products of 2250 cc. of ether C, among other constituents which are being further examined there was identified, as a major product, αβ-dibromovinylethyl ether (1 gram), which must have arisen from vinylethyl ether, CH<sub>2</sub>: CH<sub>2</sub>: CH<sub>3</sub>, b.p. 35°·5, present in the original ether. Vinylethyl ether was also present to a similar extent in freshly prepared ether, direct from the manufacturing still, which had never been exposed to light. It doubtless owes its origin to vinyl alcohol (acetaldehyde) functioning in the same way as ethyl alcohol in the Williamson process.

The instability of vinylethyl ether to acids with production of acetaldehyde is on record, but it also develops aldehyde on storage without acid and reacts towards Schiff's and Tollens' reagents as an aldehyde

The question as to whether vinylethyl ether is the first product of the action of light on diethyl ether as postulated by Wieland is receiving attention. It may, however, be recorded that an old sample of solvent ether which was rich in peroxides—equivalent to 5.6 gm. of hydrogen peroxide per litre—contained a small amount of vinylethyl ether, as was shown by isolation of its bromine addition product.

HAROLD KING.

#### The Glaciers of Dauphiné.1

N NATURE of Mar. 27, 1926 (vol 117, p. 456), an account was given of the important glaciological work carried on by the French Direction Générale des Eaux et Forêts on the principal glaciers of the chain of Mont Blanc A further volume of results has now been published relating to similar work on the glaciers of the Alps of Dauphiné, those descending from the great peaks de la Meije, les Écrins, and Mont Pelvoux It will be remembered that the principal glaciers in question are as follows On the north of the Meije group of peaks, facing the Romanche valley, in which is situated La Grave, there are the glaciers de la Meije, de Tabuchet, de l'Homme, de Rateau, du Lac, de la Girose, and du Mont-de-Lans; on the south side, facing the valley of Vénéon, is the glacier de la Selle, from the north-east and north-west flanks of les Écrins respectively descend the glaciers Blanc and de la Bonne Pierre, and between les Écrins and Mont Pelvoux, north of the latter, the glacier Noir, while from Mont Pelvoux and its flanking companion peak the Ailefroide descends on the west the glacier de la Pılatte

All these glaciers have been under observation, survey, and accurate measurement since the year 1911, and some of them since 1909, with the exception of the two first War years, 1914 and 1915, right up to the present time, the report giving the results up to 1924. In addition, the glaciers of the Grandes Rousses group, north-west of the Meije-Écrins-Pelvoux chain, those of Saint Sorlin, des Quirlies, des Malâtres, du Grand Sablat, de Sarennes, and des Rousses, have also been observed.

From the commencement in 1909, when the glaciers de la Selle, de la Girose, and du Mont-de-Lans were studied, it was obvious that the period of retrogression, hitherto for many years so obvious, was coming to an end, if it had not actually terminated, so that the time chosen for this great survey of glaciological movement was most propitious. The official observers of the Département des Eaux et Forêts had the advantage of the collaboration of Profs Blanchard and Flusin of the University of Grenoble, and of Prof. Bénévent of the École Supérieure

The first results obtained in 1909 showed that while the glacier de la Selle was still very slightly in retreat, the Girose and Mont-de-Lans glaciers had really begun to advance, the snout of the last-mentioned glacier being thrust forward nine metres beyond its position in 1908. Moreover, the general appearance of both glaciers had changed enormously, much of the ground hitherto left bare at the sides during the retreat having been recovered. When observed again in the summer of 1910, a very stormy year of great snow blizzards, all three glaciers showed a clear advance.

In 1911 the observations were extended to the glaciers de la Meije, du Lac, du Rateau, and the six

No. 3032, Vol. 120]

, da se

glaciers already named of the Grandes Rousses, and the advance found to be general, a clear frontal (snout) advance of all the glaciers being revealed by the measurements, together with a great augmentation of the upper snowfields and névé. The next summer, 1912, was very wet and cold, and avalanche residues persisted to quite an unusual extent, so that the snow augmentation above, on, and about the glaciers was very remarkable.

In 1913 the observations were further extended so as to include the glaciers de la Pilatte (the Refuge Carrelet above La Berarde being the base of operations) and de la Bonne Pierre, and similar advances with all were observed, except in the case of the last-mentioned glacier, which still showed a slight retreat

The War at first prevented the regular continuance of the work, but happily means were found in 1916 to recommence the observations By this time all the Dauphiné glaciers had advanced considerably, even the Bonne Pierre having thrust its snout forwards by ten metres The glacier de la Selle had so greatly enlarged that all the stakes (jalons), ladder-scales, and other fiducial marks were totally buried and lost; and the avalanche snow from the Col de la Lauze (the well-known glacier pass at the head of the Girose glacier, by which one passes over from La Grave to St Christophe on the Le Berarde road) had so accumulated on the St. Christophe side over against the de la Selle glacier as to have obliterated completely the medial moraine of the latter. The 1917 observations also afforded similar results, but without the exceptional snow deposits.

The general advance of the Dauphine glaciers at this time is more remarkable than that referred to in the previous report on the Mont Blanc glaciers, inasmuch as the precipitation is much less than that occurring in the Chamonix district. At La Berarde, for example, the average is only half what it is at La Tour at the northern end of the Chamonix valley In the summer of 1918, however, it began to look as if the advance were only a secondary one, and not to be compared with the great advance of the seventeenth century, which began in 1580, or the later one which showed its maximum in the beginning of the nineteenth century. For the growth had slackened or ceased in many cases by 1918, although some of the glaciers still showed a clear advance, for example, the glacier de la Bonne Pierre and the glaciers Blanc and Noir, which had now come under observation and had exhibited a thrust of snout forwards by so much as ten metres each The year 1919 was a great snow year, so much so that the glaciers and their moraines were too much snow encumbered to enable any valuable conclusions to There were two exceptions, howbe drawn. ever, for the glaciers de la Meije and Tabuchet showed very clearly increases in length of no less than seventy and thirty-five metres respectively, and the Meije had also thrown up a new moraine ten metres high. By 1921, nevertheless,

į

retrogression was manifested, the Girose glacier having retreated six metres since 1919, the Meije nine metres on one tongue of its snout and thirty on the other, the Rateau by two metres, and the Tabuchet by twelve and twenty-five metres on its two fronts

In reality, however, this retrogression was but temporary, caused mainly by the rarity of snow in the winter of 1920-21 and the relative dryness of For when the summer of 1922 came round the glaciers had all again clearly advanced, or had at least formed a front of clear blue ice as if the minimum were passed and advance were looming That this view was correct has since ahead again been clearly proved by the measurements made during the summers of 1923 and 1924 In 1923, for example, the Grandes Rousses glaciers showed unmistakable frontal advances since their last measurement; for example, the glaciers des Rousses and des Quirlies had each elongated by three metres, and the Saint Sorlin by fourteen metres In 1924 the glacier du Mont-de-Lans exhibited an advance of sixteen metres since 1921, the glacier du Lac ten metres, the glacier de la Meije seven metres, the glacier du Tabuchet thirteen metres, and the glacier de l'Homme five metres. The positions of 1919 have thus not only been recovered but also passed, and the fronts were all of clear, beautifully clean ice, while a considerable increase of superficial rapidity of movement was also observed, a sure sign of advance

Hence it seems certain that we are now really in a period of true advance of the glaciers of the Dauphmé Alps, a result in line with that derived from the Mont Blanc glaciological survey. The work on these Dauphine glaciers has been much more arduous, however, as the writer can testify from having actually seen some of the observers at work. On one occasion a number of them were lost for five hours in a terrific snow blizzard on one of the Meije glaciers, and only reached the refuge hut when frost-bitten and on the point of exhaustion. Such accurate work as is recorded in this report, carried out under such conditions, will be appreciated by all who read it, and most of all by those who know the ground, and the danger and tragic history of this group of mountains, the terrible Meije and its sister peaks, the last of the great Alpine peaks to be trodden by the foot of man A. E. H. TUTTON.

# The Development of Human Physiology. By Dr. C G. Douglas, C.M.G., F.R.S

In physiology our task is to study the nature of the phenomena which characterise normal life, as shown in the individual organism. At the outset it would perhaps seem presumption on our part to turn our attention to what we must admit to be the most complicated and highly-developed organism, namely, man, before we have been able to elucidate at least the main features of the life-process of more lowly forms; should we not do better to argue from the simple to the complex?

In the last fifty years we have seen the wide extension of what I may term the analytical method of physiological investigation, the attempt to differentiate the various components in the complex system which we call life, and to study in detail each of these components in turn and to render clear the The organism is in phenomena peculiar to each this method treated as a series of systems—we speak, for example, of the nervous system, the circulatory, the respiratory, and the excretory systems—which, though no doubt but parts of a whole, are yet capable of being treated within limits as independent In pursuing this method we have a perfectly definite aim, for we are trying to establish elementary facts about the different parts of the body without some knowledge of which we feel, and feel rightly, that a general conception of the whole is impossible. No one can deny that we have acquired in this way a mass of information which is essential to the whole study of physiology, nor is there any reason to suppose that the future will witness any diminution either in number or importance of the contributions thus made to knowledge.

 $^{1}$  From the presidential address delivered to Section I (Physiology) of the British Association at Leeds on Sept. 2

The bulk of this information has been attained by the deliberate and careful investigation of animals by experimental methods, and as I am going to plead the cause of human physiology, may I say at once, lest any one should misconceive my purpose, that I do not believe that progress in physiology and in medical science to the lasting benefit of mankind is possible without employing such methods. But, while acknowledging the great debt which we already owe to these investigations, and my firm conviction that their further prosecution will be fully justified in the future, I have to face the question whether the method has not in reality some limitations

We are bound, I think, to admit frankly that direct observation by methods involving operative procedure on the anæsthetised animal cannot by itself give us the full answer that we require. I have defined physiology as the study of the nature of the phenomena which characterise normal life, and normal life involves constantly varying activity of all the different organs of the body Under the influence of an anæsthetic our subject is no longer normal, and we have perforce deliberately to close our eyes to that fundamental aspect of life—ceaselessly varying natural activity. We are forced to adopt methods of investigation which are essentially highly artificial; the stimuli which we employ are usually coarse, and the changes to which we subject the organs gross, compared with the delicate alterations to which these same organs respond in natural life

If we are to understand life we must ultimately adopt methods of investigation which do not interfere with the normality of the organism or its power of self-maintenance; and clearly, so long as

we keep this aim before us, we are perfectly justified in making our observations on any animal the study of which we think will help to solve our problem. The conditions will be satisfied so long as our experimental treatment, whether that involves operative procedure or not, does not materially prejudice the delicate regulation of bodily functions which is so evident in the normal The point which I want to intact animal. emphasise is that, in the study of normal physiology, man is in many instances a far more advantageous subject for investigation than are the lower

It may be urged that, so far as concerns the natural variations in activity of everyday life, we may study the lower animals just as profitably as man. But can we guarantee that any animal, even though highly trained, will provide the particular state of activity that we may require at the moment? Man at least will conform with our requirements, and will maintain at request either rest or any degree or type of activity which we may desire. What is more, he, though himself the subject of investigation, can help us to make our observations, and very often intelligent co-operation on the part of the subject may render easy experimental procedure which would otherwise be impossible. We gain, too, the advantage of learning the subjective impressions of the person on whom we are making our experiments.

A review of the advances made in recent years in our knowledge of the general metabolism and energy exchange, of the regulation of the respiration and circulation, of the function of the kidneys, digestive organs, and nervous system, and of the general adaptation of the body to alteration of environment justifies the assertion of the advantage derived from studying the human subject; for experiments on man have already thrown much light on the actual quantitative changes in organ activity during normal life, on the close functional linkage of different organs and on the power of adaptation to altered circumstances. Direct experiments on anæsthetised animals, on the other hand, very often afford information about potentialities in the body rather than actualities.

The more we examine the normal behaviour of the body the more is it brought home to us that the maintenance of the natural life and integrity of the organism depends on the closest co-ordination of all its different parts; all the organs are interdependent, and can have no real existence save as active components of a corporate whole. Life consists of a delicate balance of all the different functions, a balance that is being continually adjusted so as to ensure the maintenance of the true functional capacity of the organism in its struggle for self-preservation in a constantly varying environment. As an agent in securing this exquisite co-ordination a physico-chemical change in the blood stream may at one moment be prominent, at another moment a nervous reflex. Very frequently both factors co-operate, the physicochemical change ensuring perhaps strict quantitative co-ordination of activity, the nervous reflex offering the advantage of speed and simultaneity of response in parts of the body remote from another. The two factors are not antagonistic, one is not gradually supplanting the other, but each plays its part in its own peculiar sphere

When we recognise the exactness of the coordination of the different functions in normal life, we cannot fail to appreciate the relative cludity of some of the experimental methods we are forced to use in physiology. Methods that interfere with the mutual interdependence of the different organs can only give us a partial insight into the problem of life, and if we use these methods, we must correct the impression that we gain by comparison with the true normal.

When we review the development of physiological thought in the last quarter of a century, we cannot close our eyes to the fact that investigations on man are becoming of increasing importance, and that the contribution made by human physiology does not involve mere matters of detail. There is something of far more importance than that, for the evidence of balanced interaction of the functions of the different organs with the preservation of the functional integrity of the whole, which is so convincingly brought home to us in experiments on the human subject, has made us appreciate that in physiology the organism as such, be it man or one of the lower animals, is our unit, and that, whatever methods we may employ in our investigations, we must keep that essential fact before us. In the problem of what is meant by life we have set ourselves the most complicated puzzle in existence. I firmly believe that human physiology, limited though our knowledge may as yet he, has already given us a vague glimpse of the final picture which we hope to complete, and has put us in a better position to fit together the individual fragments, the tiny components of the puzzle, which we have been accumulating in such profusion in years past.

The truth is that we cannot confine ourselves exclusively to any one method in physiological investigation. Unless we deliberately study the normal organism in its entirety, I do not see how we can gain any adequate conception about what is really implied by life, but once we have begun to gain that conception we can employ the methods of detailed analysis about which I have spoken earlier with hope of real success There has been a tendency of late to differentiate the subject of bio-chemistry from physiology, but this distinction, though it may have the merit of administrative convenience, can have no real justification if the ultimate aim of the physiologist and bio-chemist is, as I suppose, the same, namely, the investigation of the nature of living processes Physiology and bio-chemistry in fact merge into one another, and if we call to our aid the resources of chemistry and physics, that need not imply that we are any the less physiologists, but we have to be on our guard that we do not by imperceptible degrees turn from the path of biology into that of pure chemistry and, in so doing, miss the goal that we set out to attain. If an example is needed of the application of

- NE

chemical and physical methods of investigation to the normal living organism, I would point to the work that has been done on human physiology, for it seems to me that a just claim may be made that in that there is represented at least one aspect of true chemical physiology.

In our enthusiasm for research we are apt to overlook the fact that unless our teaching can keep pace with our research the general advance of learning must be seriously impeded. I cannot help feeling that our teaching of physiology would be more satisfactory if human physiology occupied a more prominent position. I am not thinking so much in this connexion of advanced teaching, for the number of students who take advanced courses is relatively small and it is fairly easy to arrange suitable work for limited numbers. The great majority of students who take up the study of physiology do so as a preliminary to a medical career, and but few of them in the end pass on to advanced courses, and it is of the elementary teaching of physiology required as a preliminary to the study of clinical medicine, or an antecedent to more advanced honours courses, that I wish to speak.

So far as the theoretical side of physiology is concerned, books enough and to spare are available; and if the student is dissatisfied with his textbook or his teachers he can turn, unless he is appalled at the prospect, to the ever-increasing number of monographs, reviews, and special volumes which offer to him information on almost every conceivable branch, however obscure, of physiology. It is, I think, the practical instruction in physiology with which we may legitimately find fault. We are, I suppose, in part tied by tradition, in part handicapped in our laboratories by the accumulation of apparatus of bygone days, and it is easy to point to lack of funds as an excuse for continuing in the same path as those who preceded us. The fact remains that so far as elementary practical physiology, as distinct from bio-chemistry, is concerned, reliance is still largely placed upon an experimental treatment of some of the rudimentary phenomena exhibited by amphibian muscle and nerve I do not deny that some of these experiments do afford information which is of value to the student, but I am also prepared to maintain that others are merely artificial, and but relics of the past that would be better omitted, and that they in no way represent the viewpoint of the present day in this branch of physiology. But though experiments on muscle and nerve still figure largely in the physiological curriculum, it is noticeable that simple experiments illustrating the progress of more recent years are gradually being introduced, and that in some laboratories a far more serious attempt has been made to remodel the curriculum than in others, and to afford an opportunity for gaining acquaintance with some of the facts of human physiology

Such a change in outlook is very welcome. When dealing with a subject which is so rapidly progressive as physiology, I feel that we are bound to reconsider our methods of teaching at intervals,

if we are to render those whom we instruct reasonably conversant with the actual state of knowledge at the time, mere addition to the curriculum is of no use, what is needed is reconstruction. Do not think that I say this in any carping spirit. After all, some facts have become so firmly established in the past as to have become axiomatic, and we must be content to accept many of these without constant repetition of their proof if time is to be found to give the student some indication of the experimental developments which have led to alteration and extension of our earlier conceptions. If practical courses of instruction are to play their full part and not degenerate into simple exercises in skilful manipulation, they must be brought into line with current physiological thought, they must, even though the experiments be simple, help to convince the student of the meaning and truth of what he reads I am certain myself that a serious attempt to incorporate even in elementary courses experiments on human physiology will be amply justified

I confess frankly that in my own case if I want to understand the facts of physiology I have to think of what they might mean to me in my own person; I cannot think easily in terms of lower animals I have got to translate the information before I can use it. I do not believe that I am peculiar in this respect Many a student would, I am sure, acquire a deeper and more real interest in physiology if his attention was directed to some of the essential facts of human physiology at an early stage in his instruction Show him something of what really happens in himself in the natural course of his daily life, awaken his curiosity about the way in which these events are actually accomplished, and he will then more readily understand the significance of what he learns from other sources. As it is, he runs the risk of being overwhelmed by the literature of the subject that he is studying and of losing himself in details which he cannot place in the right perspective: he too often fails to see the wood for the trees. The quantitative interdependence of function in the body can be well illustrated by simple experiments in human physiology; and a more convincing introduction to those quantitative conceptions which must form the basis of physiology, as of other branches of natural science, can be gained, I think, in this way than by, say, a few quantitative bio-chemical analyses which, essential though they may be in themselves, can scarcely be more than exercises in method in the early days of a student's career

These students are for the most part going to follow the profession of medicine, and in the short time available our aim must be to develop their powers of thought and initiative that they may be the better equipped to face the future when they go out into the world, and if they leave us with only the recollection of a medley of seemingly disconnected facts, it is quite intelligible that they may fail to grasp what physiology really means, and that a gulf, for which there can be no justification, will deepen between physiology and medicine. Physiology is not medicine: the physician sees a

side of life which the physiologist does not meet in the cold alootness of the laboratory. The art of medicine is not based merely on the application of skilled technique, it demands in addition a full and sympathetic comprehension of human nature with all its hopes and fears, its frailty and courage. Yet the more the physiologist can find out about the characteristics of normal life the greater will be his service to medicine, for a knowledge of the normal cannot but help us to estimate with greater certainty the influence of the abnormal, and the underlying principles of adaptation of organ activity which we as physiologists recognise in the functional changes which exhibit themselves in everyday life, and, in the reactions to alterations of environment, have their counterpart in medicine in the natural efforts at compensation for the effects of injury or disease, a compensation which it must be the aim of the physician to encourage and assist.

There is yet another field in which scope may be

found for human physiology. In the growing complexity of the modern world the improvement of the general standard of life is a matter which appeals to all of us. Physiologists have already played a prominent part in investigations into the means by which conditions may be improved and risk reduced in industrial processes, into the factors which affect the efficiency and welfare of the working classes, and into the influence of diet on health Problems such as these, the solution of which is of direct benefit to the community at large, call for the practical application of physiological principles We ought not to regard applied physiology as something distinct, as something to be divorced from the more academic study of theoretical physiology, it should be looked upon as the natural extension of our researches in the laboratory. These practical problems in their turn often suggest new lines of inquiry, new methods of approach, by which the science of physiology may be still further advanced.

#### Obituary.

Prof. R. A Lehfeldt.

PROF. ROBERT ALFRED LEHFELDT, professor of economics at the University of the Witwatersrand, Johannesburg, whose untimely death is reported from Cape Town, was born at Birmingham on May 7, 1868, and thus was in his sixtieth year. Lehfeldt's initial education and pursuit of science was largely the outcome of strenuous personal endeavour. Obtaining a scholarship at St. John's College, Cambridge (1886), he secured a first class in both parts of the Natural Science Tripos. Meanwhile he read for a London degree, eventually taking his D Sc. in physics. On leaving Cambridge, Lehfeldt occupied a post as demonstrator in physics at the University of Sheffield (then Firth College); later, he became professor of physics at the East London Technical College, remaining there until appointed (1906) to the chair of physics, Transvaal Technical Institute, Johannesburg, a post resigned on his acceptance (1917) of the professorship of economics in the University of the Witwatersrand.

Among several papers by Lehfeldt published in the *Philosophical Magazine* are . "A Potentiometer for Thermocouple Measurements" (1903), and "The Treatment of Electrodynamics" (1909). He translated from the German, Van't Hoff's lectures on theoretical and physical chemistry (3 vols., 1898–1900), also Nernst's theoretical chemistry (Macmillan, 1904), revised m accordance with the fourth German edition. He was the author of a text-book of physical chemistry (general theory) in the series edited by Sir William Ramsay (1904, a new impression appearing in 1920). Lehfeldt was a valued worker for the Royal Society's "Catalogue of Scientific Papers," series 1884–1900. His services are referred to, along with other coadjutors, in Vol. 13 (1914).

In certain fields of economics Lehfeldt was a persistent advocate. The *Economist* published on Nov. 6, 1926, the first of a series of five articles of his (afterwards appearing in pamphlet form) entitled

"Controlling the Output of Gold." A proposition embraced the setting up of an international commission charged with the duty of buying out and becoming the owner of the gold-bearing and gold-producing ores of the world. Lastly, the *Economist* on Sept 24, 1927, published suggestions leading to a more economic mode of currency in England.

In early years Lehfeldt was reticent, difficult of approach, and somewhat inclined to moodiness. Unfortunately, it would seem that these general characteristics, so far from diminishing with time, gathered force. Notwithstanding, he accomplished much sound work in science and in cognate subjects, and his old associates at home and those overseas will deeply deplore his premature decease

PROF. LUDWIG DARMSTÄDTER, director of the State Library, Berlin, died on Oct 18. A native of Mannheim, Darmstädter was educated at the Universities of Heidelberg, Leipzig, Berlin, and Paris. About twenty years ago he presented to the State Library, Berlin, his valuable collection of porcelain and of autographs and other documents relating to men of science. This collection, known as the "Dokumenten-Sammlung Darmstadter," has developed until it is probably the largest of its kind. His best-known work is the "Handbuch zur Geschichte der Technik und Naturwissenschaften."

WE regret to announce the following deaths:

Dr. M. Bamberger, emeritus professor of inorganic chemistry at the Technische Hochschule in Vienna, on Oct. 22, aged sixty-six years.

on Oct. 22. aged sixty-six years.
Dr. R. A. Herman, lecturer in mathematics in the University of Cambridge, on Nov. 29, aged sixty-six years.

Lord Kenyon, K C.V.O., president of the National Museum of Wales, on Nov. 30, aged sixty-three years. Prof. Perley F. Walker, dean of the school of engineering of the University of Kansas since 1913, who was known for his work on steam and gas power engineering, on Oct. 17, aged fifty-two years.

#### News and Views.

AT first sight a student referring to a text-book would think that the evolution of the Proboscidea is a comparatively easy matter to understand. The picture of a straight line of descent from the little Moeritherium, through Palæomastodon, Mastodon, Stegodon, and so on up to the later mammoths and elephants, seems very easy to read Closer examination, however, and a reference to the enormous literature on the subject, reveal a most complicated state of affairs. There is an immense number of families, genera, species, and sub-species of elephants already described, many of them still inadequately known, there is still no very clear agreement of what constitutes a specific character in an elephant, and there are many widely diverging views as to the real relationship of the various forms one to another. As species of elephants, e.g. E. antiquus, E. trogontherii, E. primigenius, E. meridionalis, are so often used as time markers, it is essential that we should have a clear idea as to what they are and as to their interrelationships. Yet we find specimens described as intermediate by some authorities and the statement hotly denied by others.

THE fact is that the taxonomy of the elephant group is in the greatest confusion Prof. Osborn's forthcoming memoir may confidently be expected to clear up the situation in some degree, in that it will present the facts so far as they are known at the present time. It cannot be expected to be a final pronouncement, because the evidence is not yet complete. Facts are still needed, and every new one that comes to light is important. The Upnor elephant, for example, now mounted in the British Museum, has yielded some new facts, and rather surprising ones, to what we know about E. antiquus. In producing some new facts, Prof. Dart's description in the Supplement to this issue of Nature of new proboscidian material from South Africa is therefore greatly welcome. If this most interesting discovery adds for the moment to our perplexity, it is nevertheless additional evidence which, in time and with the discovery of further material, will in the future yield its quota to the solution of the filiation, distribution, migration, and general knowledge of the group.

AT the anniversary dinner of the Royal Society, held on Nov. 30, Mr. Baldwin, the Prime Minister, as principal guest, proposed the toast of the Society, of which he was recently elected a fellow. It should be said that the inclusion of certain persons not actually engaged in scientific pursuits is a practice sanctioned by long usage In the Society's original statutes of 1663, whether wisely or not-and there were mundane considerations—it was provided that every one of His Majesty's subjects having the title and place of baron, or any other higher title and place, and every one of His Majesty's Privy Council, might be elected. With slight variations these intentions were preserved down the years, until. in course of time, such persons formed a panel or privileged class. As regards foreign members, the procedure was different altogether. In 1765 it was resolved that no foreigner be proposed for election "that is not known to the learned world, by some publication or invention". Discussion in 1873 on a motion to require in the privileged class, "evidence of ascertained special power and disposition to forward the aims of the Society from exceptionally personal, or official advantages of position," ended by limiting the privileged class to princes of the blood royal and members of the Privy Council

STATUTES enacted by the Royal Society in 1902, and still followed, abolished the clause relating to privy councillors, simply providing that once in every two years the Council may recommend not more than two persons who "either have rendered conspicuous service to the cause of science, or are such that their election would be of signal benefit to the Society." It is permissible to say that the implications of this statute seem clear enough opportunities of the chief officer of State in the scientific arena are recurrent and understood: as political moves they would be an affront to science. No one doubts that Mr Baldwin will honour the bill. and that inclination and temperament will be allied in furtherance of aims which bring science into touch with schemes that affect the national well-being We are mindful that Mr. Joseph Chamberlam, as a Government official, passed the word that research and preventive measures in tropical diseases were necessary and must be undertaken. What followed made history

A CORRESPONDENT recalls the interesting fact, in connexion with Mr. Baldwin's election, that in recent times three precedents can be recorded for the election of a Prune Minister into the Society whilst holding the seals of office The instances are: Mr. Disraeli, elected on Feb. 10, 1876; Mr. Gladstone, elected on Jan 13, 1881, the Earl of Oxford and Asquith (then Mr Asquith), elected Nov. 5, 1908 The first-named was formally admitted by Dr. J D. Hooker on June 1, 1876, that being the day fixed for the election of ordinary fellows. Amongst these (and surviving) were Prof H E. Armstrong and Sir David Ferrier. Mr Gladstone was admitted on May 19, 1881, on which occasion William Crookes read a paper, "On Discontinuous Phosphorescent Spectra in High Vacua." Sir William Thiselton-Dyer, who had been elected a fellow in the previous year (1880), survives, and, indeed, may have witnessed Mr. Gladstone sign the charter book.

Considerable interest has been aroused by the report in the press that concessions were believed to have been granted to a British syndicate for the purpose of utilising the vast mineral resources of the Dead Sea. This interest was reflected in the very pertinent questions put in Parliament a few days ago. From the reply given in the House of Commons by Mr. Ormsby-Gore, it appears that although it has been decided in principle to grant a concession to

certain individuals, the terms and conditions are still under negotiation. The potassium salts of commerce are derived largely from the Stassfurt deposits in Germany. At the outbreak of the War in 1914, these supplies were closed to the Allies and a serious dearth ensued. The waters of the Dead Sea are heavily charged with mineral salts. They are estimated to hold in solution some 2000 million tons of potassium chloride, a quantity that may be regarded as practically inexhaustible from a commercial point of view. In the event of war, these supplies, if accessible, might be extremely valuable to the British Empire, and considerable anxiety has been manifested lest Germany or some other foreign power should acquire controlling interests over these supplies.

LORD LOVAT stated in the House of Lords that the Government is fully aware not only of the economic importance of the Dead Sea deposits, but also of the political questions that may arise in the event of these deposits being worked. This, in so far as it goes, is reassuring. It must be borne in mind that the whole scheme is at present merely in an experimental stage. Whilst, as a purely chemical proposition, it may not be difficult to prepare the different salts in a sufficient state of purity to meet modern requirements, the placing of these salts upon the European market at competitive prices may be no easy task. The level of the Dead Sea is some 1300 feet below that of the Mediterranean, and Jaffa. the nearest port, is hemmed in by rocks to seaward which effectively bar the approach of any but the smallest boats. Thus the problem of transport alone, in a country which is devoid of fuel, in the face of the ready accessibility of the Stassfurt deposits, is one of considerable magnitude.

THE Institute of Chemistry of Great Britain and Ireland, which was founded in 1877 and incorporated by Royal Charter in 1885, celebrates its jubilee on Dec. 14 and 15. In the proceedings the fellows and associates of the Institute will be joined by members of nine allied chemical societies and institutions and their ladies. On Wednesday, Dec. 14, there will be a conversazione and reception by the president, Prof. Arthur Smithells, and Council of the Institute, and on the following evening a dinner, at which the president will occupy the chair, both events taking place at the Wharncliffe Rooms, Hotel Great Central, Marylebone. For this year the jubilee dinner will take the place of the annual Chemical Dinner. An exhibition of films illustrating British industries in which chemistry is applied has been arranged for Thursday morning, Dec. 15, and on both days the Council Room, Library, and Laboratory at 30 Russell Square, W.C.1, will be open to members of the participating organisations. Documents, portraits, apparatus, and prints of historical interest will be on view, and the Institute's collection of lantern slides illustrating the history of chemistry will be displayed. On Dec. 15, the Master and Wardens of the Worshipful Company of Salters will entertain the officers of Institute and representatives of other societies at |

luncheon. The Institute of Chemistry, which is well known as a body which grants certificates of competency in various branches of the profession with the object of maintaining a high standard of scientific and practical professional, and deals also with questions of status and professional conduct, now has a membership roll of more than 5300 fellows and associates practising in all parts of the Empire, and 800 student-members. There are sixteen local sections, and a number of honorary corresponding secretaries who act for the Institute in the Dominions and Colonies, and in the Empire of India.

IMPERIAL CHEMICAL INDUSTRIES, LTD, has taken yet another important step in the direction of promoting closer relations between so-called 'pure' and 'applied' chemical research. By its establishment of a research council, which will function as an advisory board and clearing house for ideas, a close hason will be effected between industry and the universities. The connexion thus strengthened between those engaged in academic and industrial pursuits provides a stimulus for the flow of vitalising force in both directions; not only will the scheme lead to efficiency of action and economy of effort in the attack on industrial problems, but it should also lay the foundations of a greater appreciation of the industrial situation by academic research workers. This is the first body of its kind to be established in Great Britain, although the value of similar organisations has been amply demonstrated in other countries. The scheme will doubtless play a significant part in helping to place British practice on more than competitive terms with modern achievements and organisations elsewhere. The council will be presided over by Sir Alfred Mond, and the other members will be Dr. G. C Clayton, M.P., Col. G. P. Pollitt, Mr. J. Rogers, Dr. F. A. Freeth, Dr. E. F. Armstrong, Dr. R. E. Slade, Mr. H. A. Humphrey, Sir Frederick Keeble, Prof. F. G. Donnan, Prof. R. Robinson, Prof. W. A. Bone, Prof. F. A. Lindemann, and Dr. E. K. Rideal, with Major A. E. Hodgkin as secretary.

On Nov 23, Sir Alfred Mond gave his presidential address to the Institute of Fuel, which has resulted from the union of the Institute of Fuel Technology and the Institution of Fuel Economy Engineers. He announced that Mr. Frank Hodges would be the new president, and gave an account of the plans and policy of the new body. The address, which was of a general character, dealt with economic rather than scientific problems. There was, however, a hint of a method, now under probation, for reducing the ash of coal to 2 per cent—an achievement so desirable that it seems too good to be true. A new application of pulverised fuel was mentioned—the use of coal dust in place of oil in the Diesel engine The realisation of such an engine might open a new vista to the coal trade. Sir Alfred advocated more study and care to prevent size reduction of coal in transport and handling, for this usually involves a diminution in market value. On the economic side he pleaded for amalgamation of units, for reorganisation of the coal industry, for reduction of the personnel by pensioning the older men, the relief of rates, taxes, and transport costs, the assistance of the State in raising the capital necessary for modernisation, as, for example, in the case of coke oven installations.

Readers of Nature will note with special interest Sir Alfred Mond's views on industrial research—his advocacy of its intensification by the use of whole teams where now individuals work. This he regards as necessary not merely to ensure progress but even to maintain our position. The coal industry seems to offer a wide field for the scientific advancement which is necessitated by international competition applies both to production and selling Thus he holds that the sale of coal of a guaranteed uniform standard would assist the export trade more than the cutting of piices, which has been the normal economic weapon of our collieries The programme of this meeting of the Institute of Fuel was interesting, and the papers of importance to actual problems. The aims of the new body are wholly beneficent, but appear to be covered by already existing organisations. Opinions differ as to whether it can accelerate technical progress. So far as the scientific worker is concerned, the multiplication of institutions, with attendant drain on purse, time, and energy, may hinder as much as help.

A PAPER on national electricity supply was read to the Institute of Fuel on Nov 23 by Sir Philip Dawson He pointed out that whilst in Great Britain only 40 per cent of the total motive-power required for industry is electric, in Germany the percentage is 70, in the United States 65, and in Belgium 56. In Great Britain large reserves of coal remain unworked because of their high ash content. They could easily be worked with the rest of the seam and sold at a cost of from four to five shillings per ton at the pit's mouth. This fuel has a calorific value about double that of the brown coal so successfully utilised in Germany, but so far little or no attempt has been made to utilise it in Great Britain. In the future these poor qualities of coal, which it does not pay to transport, should be used in the form of pulverised fuel to produce electricity at the colliery. In England, only 14 per cent. of the coal mined is cut mechanically. This compares with 47 per cent in Scotland excess gas produced in steel works should be utilised for generating electricity, as this could be profitably supplied to the network controlled by the Central Electricity Board.

SIR PHILIP DAWSON stated that we are only beginning to reap the benefits of co-operation and co-ordination in the generation and transmission of electricity. Wherever interconnexion has been carried out, it has resulted in greater safety and more perfect continuity of supply. In Sir Philip's opinion, the result of the 1926 Act should bring about, in the best sense of the word, a national and not a nationalised supply of electricity in Great Britain. In the discussion, Sir Arthur Duckham said that for the supply network in the Clydeside area, the first scheme put forward by the Central Electricity Board, not a single colliery has offered to supply electricity to the system.

It is possible that in the future the collieries will utilise for their own purposes electric power from the network, some of which is generated by water, instead of economically generating it themselves by their own low grade fuel

ONE or two years ago, Dr Karolus, of Dresden, claimed to have achieved television by means of apparatus which transmitted 100,000 units of the image in one-tenth of a second We now learn from the Times of Nov. 30 that his system of transmitting photographs and papers which may be coloured—except green, blue, and mauve, which are not recommended by telegraph wires has been adopted by the Austrian telegraph department The pictures sent may portray persons or drawings, cheques, structural plans, documents, or writings by hand or type. The size of the picture or type must not exceed 4 inches by  $7\frac{1}{2}$  inches, the minimum being 4 inches by  $1\frac{1}{2}$  inches The paper must be opaque and the writing clear and easily read. It is stated that the largest strip will accommodate 400 words in pearl type. The charge for the transmission of the smallest permissible picture from Vienna to Berlin is 7s. 11d, each additional 12 square inches costing 2s. A reduction of about 25 per cent is made if the picture is transmitted during the night hours, that is, between 9 P.M and 8 A.M. The Siemens' Electrical Company, which is producing the apparatus, has modified Karolus's original system Full details will be awaited with interest, as the transmission of coloured prints and photographs by telegraphy has hitherto not reached the commercial stage.

Most hearty congratulations are due to the veteran Prof. W. Cawthorne Unwin, F R.S., who, on Monday next, enters on his ninetieth year. Born at Coggleshall, Essex, he was educated at the City of London School, and on leaving became a pupil in the firm of William Fairbairn, Manchester. Next he undertook the managership of some engineering works, thereafter filling a post as an instructor in the Royal School of Naval Architecture and Marine Engineering, South Kensington He was professor of hydraulic engineering at the Royal Indian Engineering College, Coopers Hill, from 1872 until 1885; afterwards, for twenty years (and these were fruitful in effort) he taught the principles of engineering at the Central Technical College, City and Guilds of London Institute. Prof. Unwin is a past president of the Institutions of Civil and Mechanical Engineers. At the latter there hangs a portiait of him by Mr. Harold Speed.

Dr. R T. A. Innes, who is retiring at the end of this year from the post of Director of the Union Observatory, Johannesburg, was born in Edinburgh, and when a young man went to Australia. To the Monthly Notices of the Royal Astronomical Society of 1892 he contributed a paper on the secular perturbations of the earth by Mars. In 1896 he joined the staff of the Cape Observatory as secretary, librarian, and accountant. Although forming no part of his official duties, he executed three valuable pieces of astronomical work: (1) A revision of the Cape Photographic Durchmusterung; (2) a general catalogue of

southern double stars, of which he discovered 280 with a 7-inch equatorial; (3) observations of variable stars. In 1903 he was, on Gill's recommendation, appointed Director of the Meteorological Observatory of the Transvaal. Gradually astronomical equipment was obtained for the Observatory, and many of the photographs of Mr Franklin-Adams' survey were taken at the Johannesburg Observatory by Mr. Wood, Dr. Innes' assistant. Dr Innes set his heart on a large visual refractor for double-star work Owing to the difficulty of obtaining optical glass and to the War, he suffered the disappointment of long delay; and it was only two years ago that a 26-inch refractor was received. He continues his interest in the motion of sun, moon, and planets, and the cause of the small but persistent differences from tables based on gravitational theory Following the example of Gill, he has welcomed at Johannesburg astronomers from the northern hemisphere, where he is able to supply sky and equipment and thus makes up for a small staff

The seventieth birthday of Prof. S. G. Navaschme, the distinguished botanist, will be celebrated in Moscow on Dec. 21 at a special meeting to be held in the University, where congratulatory addresses and greetings will be presented to him. Prof. Navaschme is a foreign or corresponding member of a number of national and botanical societies, and his botanical work is highly esteemed over a wide circle. Letters or telegrams of congratulation should be addressed to Prof. M. J. Golenkin, director of the Botanic Garden, University of Moscow, U.S.S.R.

On Nov. 30, the portrait of Prof. J. A Floming, painted by Sir William Orpen, was presented to University College, London, by the chairman of the Portrait Fund Committee, Mr. Campbell Swinton. The gift was received on behalf of the College by Lord Chelmsford, chairman of the College Committee, and Prof Coker, Dean of the Faculty of Engineering. In making the presentation the chairman gave an engaging account of the eminent artist's method of producing so strikingly successful a result. Lord Chelmsford, in acknowledging the gift, said that Prof. Fleming's life and work have shed lustre on the College, and that more than 2000 students have passed through his hands, three of whom have been presidents of the Institution of Electrical Engineers. Prof. Coker also testified to the distinguished career of Prof. Fleming, both as teacher and investigator. The chairman then presented Prof. Fleming with a copy of the portrait. In accepting it, Prof. Fleming briefly outlined the growth of his Department of the College, and stated that he intended presenting the copy to the Institution of Electrical Engineers. This he did on the following evening. The copy of the portrait was received by the president of the Institution, Mr. Page, who thanked Prof. Fleming for his gift in very cordial and appreciative terms.

At the annual general meeting of the fellows of the National Institute of Agricultural Botany at Cambridge on Dec. 2, Sir Daniel Hall, who presided as chairman of the Council, submitted the annual report and presented to Sir Matthew Wallace the John Snell

Memorial Medal for 1926 Papers were then read dealing with different aspects of the testing and control of agricultural seeds. Mr A W Monro, of the Ministry of Agriculture, dealing with the administrative aspect, recalled that the regular testing of seeds for purity and germination began in Germany m 1870 and Denmark in 1871. Ireland established an official seed-testing station in 1900, Scotland in 1914. and England and Wales in 1917. Legislative control m the United Kingdom began with the Irish Weeds and Agricultural Seeds Act of 1909, and was extended to the whole country by the Testing of Seeds Order in 1917. This was superseded by the Seeds Act, 1920. The basic principle of the Order and the Act is to let the farmer know what he is buying by compelling the seller to disclose the essential facts -origin, variety, purity, and germination - -in the case of the principal agricultural seeds Seed morchants, taken as a whole, comply readily with the regulations, but farmers who sell seeds to their neighbours are apt to ignore them. The information required by the Act is obtained by tests at the official stations - Cambridge, Edinburgh, and Belfast- or at one of the 88 private stations licensed by the Ministry. In the opinion of Mr Monro. the principal effects of the Act have been to raise the quality of the bulk of the seed supplies, so far as purity and germination are concerned, to the high standard that has long been observed by the best merchants, and to drive off the market the lower grades of grass, clover, and root seeds.

MR. ALFRED EASTHAM, the Chief Officer of the Official Seed-Testing Station for England and Wales, read a paper on the technical aspects of seed testing Essential though accuracy is in seed testing, it is now generally recognised that the efficiency of the routine work depends upon constant investigation of the underlying principles and their adaptation to the changing character of the seasons. In addition to these routine investigations, there are many special problems under examination at the Cambridge Station. Examples of these problems are (a) the loss of vitality in seeds and the bearing which storage conditions have upon the rate of loss, and (b) seedborne diseases Both are of much importance to all who are interested in seeds, and during the past four years a great deal of time has been spent upon them. A seed-testing station's first duty is to report on the purity and germination of the samples it tests; but, though high percentages of purity and germination are most desirable, too much value should not be placed upon them The nationality of the seed, its vigour, and the nature of the impurities present must be kept in view Strain is of the first importance, and, provided it is free from harmful impurities, seed of a good strain but of comparatively low purity and germination is much to be preferred to seed of a poor strain, however high its purity and germination; for the latter might easily fail to produce a satisfactory

THE Library of the Chemical Society will be closed for the Christmas holidays at 1 p.m. on Friday, Dec. 23, and will reopen at 10 a.m. on Thursday, Dec. 29.

Mr. S. Zuckerman, of the University of Cape Town, has been appointed to the research followship in anatomy, and Miss Eleanor Margaret Brown, of University College, London, to the aquaitum research fellowship, offered by the Zoological Society of London.

For the meeting of the British Association to be held next year in Glasgow on Sept. 5-12, under the presidency of Sir William Bragg, the following sectional presidents have been appointed Section A (Mathematical and Physical Sciences), Prof A W. Porter; Section B (Chemistry), Prof E C. C Baly, Section C (Geology), Mr. E B. Bailey, Section D (Zoology), Prof. W Garstang; Section E (Geography), Prof. J. L. Myres, Section (# (Engineering), Sir William Ellis; Section H (Anthropology), Sir George Macdonald, Section I (Physiology), Prof. C Lovatt Evans; Section J (Psychology), Prof. T. H Pear, Section K (Botany), Prof. R H. Yapp, Section L (Education), Prof. A Smithells, Section M (Agneulture), Dr J. S Gordon. The president of Section F (Economic Science and Statistics) will be announced later

AT an extraordinary meeting of the General Committee of the British Association, held on Dec. 2, the president, Sir Arthur Keith, in the chair, it was resolved to put forward an application for a Royal Charter for the Association. Mr. A. A. Campbell Swinton was warnly thanked for his generous offer to bear the cost of obtaining the charter. It was also resolved "that the General Committee gratefully accepts Mr Buckston Browne's generous offer to vest Downe House in the Association, and authorises the president to make any suitable arrangements for the custody of the property in the interval between the acquisition thereof and the granting of a Charter."

A LIFE-SIZE bronze statue of the late Dr. John A. Brashear, well known as the maker of numerous large telescopes and astronomical instruments, and the founder of the new Allegheny Observatory, has been placed in the rotunda of the Observatory and was unveiled on Nov. 24, the anniversary of his eighty-seventh birthday. The statue is the work of Mr. Frank Vittor, and is a gift to the University of Pittsburgh from a number of Dr Brashear's life-long friends.

The following officers and new members of council of the Cambridge Philosophical Society have been elected for the session 1927–28: President, Dr H. Lamb; Vice-Presidents, Prof. J. T. Wilson, Prof. A. Hutchinson, Prof. G. I. Taylor; Treasurer, Mr. F. A. Potts; Secretaries, Mr. F. P. White, Mr. R. H. Fowler, Mr. F. T. Brooks; New Members of Council, Mr. W. H. Mills, Mr. M. H. A. Newman, Dr. H. Hamshaw Thomas, Dr. J. Needham; New Member of Philosophical Library Committee, Mr. R. H. Fowler.

An International Exhibition and Conference on Light and Heat in Medicine and Surgery will be held at the Central Hall, Westminster, on Dec. 13-16. The work of the conference will be divided into three sections, dealing with light and heat in medicine and surgery, scientific research in relation to the practice of actmotherapy, and recent advances in optics, respectively. The exhibition will be opened at 2.30 PM, on Dec. 13 by Sir Alfred Mond. The exhibition and conference are being organised by the British Journal of Actmotherapy, 17 Featherstone Buildings, London, W.C.1, from which tickets of myitation and vouchers for reduced railway fares can be obtained.

Reference was made in our issue of April 30, p 649, to the nineteenth meeting of the Australasian Association for the Advancement of Science, to be held at Hobart during the week commencing Jan. 16. A further programme recently received enables us to give more particulars of the meeting. The presidential address by Mr. R. H Cambage will be on the development of some early Australian floras. Sectional presidential addresses are topical, and refer mainly to Australian conditions. In addition to papers in the various sections, discussions have been arranged on research in relation to manufacturing industries in Australasia (physics, chemistry, and engineering sections), animal nutrition and pasture deficiency (chemistry, agriculture, and veterinary science sections), structure of colloids (chemistry and physiology sections), the marketing of fruit (economics section), the pharmaceutical chemist in the community and micro-chemical methods in testing pharmaceutical products (pharmaceutical section).

A Rubber Exhibition was opened at the Imperial Institute, South Kensington, on Dec. 2, by Mr. Hacking, Parliamentary Secretary of the Department of Overseas Trade, and will remain open until Dec. 31. This exhibition, admission to which is free, is the first of a series of short exhibitions of Empire products which will be held from time to time at the Imperial Institute. It has been arranged in conjunction with the Rubber Growers' Association and is divided into two parts, the first dealing with the production of raw rubber, and the second, with manufacture and application. A series of specimens of wild rubber plants, which were the only source of rubber until the modern plantation system was evolved, are shown; at the present time, this source is responsible for only about 5 per cent. of the total world production. Two allied rubber products are also exhibited, i.e. balata and gutta-percha. Both of these are chemically similar to rubber, although they differ in their physical properties. Further exhibits illustrate various processes of manufacture of raw rubber. The Research Association of British Tyre and Rubber Manufacturers has contributed an exhibit showing the compounding ingredients employed in the manufacture of rubber articles, and the Ceylon Rubber Research Scheme (which has its laboratories at the Imperial Institute) illustrates various investigations in connexion with the perishing of rubber and variations in its plasticity. About fifty firms have contributed to the exhibition A film showing the production of raw rubber and its utilisation in manutacture is being displayed in the adjoining cinema. Lecture tours are also arranged for those who care to avail themselves of these facilities.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned —A jumor sccretary (male) in the External Registrar's department of the University of London-The Secretary, University of London, South Kensington, S W 7 (Dec. 16) A graduate assistant in mechanical engineering at the Wakefield Technical College-The Director of Education, Education Offices, Town Hall, Wakefield (Dec 17). A Paterson research scholar in the cardiographic department of London Hospital—The House Governor, London Hospital, E 1 (Dec. 19) An additional research fellow in the department of glass technology of the University of Sheffield—The Registrar, The University, Sheffield (Dec 23). A junior assistant at the National Physical Laboratory with a good honours degree or equivalent qualifications in engineering—The Director, National Physical Laboratory, Teddington (Dec. 24) A principal of the Constantine Technical College, Middlesbrough—The Director of Education, Education Offices, Middlesbrough (Dec.

A lecturer in inorganic and physical chemistry at the Sir John Cass Technical Institute-The Principal, Sir John Cass Technical Institute, Jewry Street, EC.3 (Dec. 31) An assistant lecturer in geography in the University of Manchester-The Registrar, The University, Manchester (Jan 11). An assistant in the department of art of the National Museum of Wales—The Director, National Museum of Wales, Cardiff (Jan. 14). An entomologist and a plant breeder in the Agricultural Department, Iraq, the entomologist must have had specialised training in entomology and experience of research work and of pest control measures; the plant breeder must have had specialised training in genetics and, preferably, experience of plant breeding work—The Private Secretary (Appointments), Colonial Office, 2 Richmond Terrace, Whitehall, S.W I. An adviser in mycology for the Bristol Province under the Advisory Scheme of the Ministry of Agriculture and Fisheries-The Registrar, The University, Bristol.

#### Our Astronomical Column.

NEW COMET — The tenth cometary discovery of 1927 is reported from Melbourne in a telegram distributed by the IAU. Bureau, Copenhagen. It was made by Mr J F Skjellerup on Dec 3 at 17 h 30 m., U.T., in R A 16h 12m 12s, S Deel 53° 57′ The comet was of the third magnitude, and had a

tail 3° long, it was moving towards the sun.

It appears very probable that this is De Vico's long-period comet 1846 IV., which has been searched for by southern observers since 1920. It so, its period is 811 years, and its perihelion passage about Dec. 15 No one has computed the perturbations of this comet since 1846, and it is possible to represent the position within a few degrees by the unperturbed elements, moreover, if identical, it would be only one-third of a unit from the earth, so any departure from its predicted place would appear exaggerated. It the identity is right, it will cross the equator about the time of perihelion, and will then pass in to high north declination The period is several years longer than the predicted one, but that causes no surprise. The comet Brorsen-Metcalf, 1847 V, returned in 1919, nine years before it was expected. Mr Skjellerup made several cometary discoveries when he lived in South Africa, but this is the first he has made since he moved to Melbourne

DETECTION OF A NEW NAKED-EYE CEPHEID.— Harrard Observ. Circular 316 contains the interesting announcement that the fourth magnitude star Beta Doradus has just been discovered to be a Cepheid variable, with a photographic light-range of 14 magnitude, and a visual one of nearly a magnitude. Miss Applegate was the first to suspect the Cepheid character, which she did by noting periodic changes in the type of spectrum; R. E. Wilson on the same grounds classed the star as a pseudo-Cepheid, not knowing of the light variation. This was not easy to detect photographically, the star's image being too large on most plates for accurate measures; but by a lucky chance, several images were found on plates with ten minutes' exposure taken in 1925 and 1926 for the light-curve of Nova Pictoris. The adopted period is 9.841696 days, and on plotting the observations with this period the variation is quite evident. The light-curve is symmetrical on each side of maximum and minimum, without any sign of a second harmonic. Prof. Bailey's visual photo-

metric observations made in 1899 at Arequipa were examined; it was found that his observations of this star showed an unusually large range, and in consequence he took a number of extra observations of it. These are now found to conform well with the adopted curve, but Bailey did not discover that the variation was regular.

Beta Doradus is one of the stars in the Nautical Almanac list, its magnitude being 3.81, spectral type Eichelberger F5p, proper motion according to -0.0031 sec in R.A.,  $+0''\cdot005$  in decl. The absolute magnitude from the period-luminosity curve is  $-1.9,\,$  giving a parallax of 0″ 0043, and a distance of 760 light-years.

SOLAR ACTIVITY DURING 1926 —The final values for the mean daily area of sunspots and Wolf's sunspot number for the year 1926 have recently been published by the observatories of Greenwich and Zurich respectively (Monthly Notices R. A.S., Nov. 1927, and Astronomische Mitteilungen, Nr. 116). The mean daily area of spots, corrected for toreshortening and expressed in millionths of the sun's hemisphere, is stated to be 1262 and the Wolf's sunspot number 63 9. Mean daily areas for periods of a solar rotation (Greenwich) and spot numbers for each month (Zurich) are also given in the respective publications.

The following table shows the progress of the present sunspot cycle since the last minimum in 1923:

Year	Mean Daily Area.	Wolt's Number.	Mean Solar Latitude of Spots
1923	55	5 8	$ \begin{pmatrix} 6^{\circ} \cdot 4^{*} \\ 24^{\circ} \cdot 4 \\ 22^{\circ} \cdot 7 \\ 20^{\circ} \cdot 2 \\ 18^{\circ} \cdot 6 \end{pmatrix} $
1924	276	16·7	
1925	830	44·3	
1926	1262	63 9	

<sup>\*</sup> Old cycle spots

t New cycle spots

The average provisional spot-number for the first six months of 1927 is 79, but since June the sun's activity has fallen off somewhat. Judging from the trend of the mean latitude of the spots—a fairly sure indication—the maximum year of the cycle should be 1928.

MEGALITHIC MONUMENTS IN THE MARIANAS -In the Scientific Monthly for November, Lieut.-Commander P J Searles describes the remarkable Lat'te or monuments composed of upright monoliths surmounted by hemispherical capitals, usually in two parallel rows of four to six stones in a row and running parallel to the seashore or a river bed The stones are of remarkable size Two of the largest monuments are in Timian. Their stones are eighteen feet in circumference at the base, and twelve feet high, the capitals being five feet high and six feet in diameter Each monolith weighs 30 tons In an unpublished manuscript of a Spanish Governor of the middle of the last century, it is stated that human bones were found in a hollow on the top of a monolith forming part of the 'House of Taga,' a chieftain who, according to tradition, buried his daughter on top of one of the monoliths Recent investigations indicate that the Lat'te were not dwelling-houses as has been thought, but monumental religious structures marking sites of ceremonies, cannibal feasts, and burnals. The mutilated condition of skeletons found in or near them points to canni-In Guam the Lat'te are connected with three areas, of which the first is the burial place, in which all the bodies are carefully orientated with feet to the water and head inland: next, an area devoted to warriors or the victims of cannibal feasts, as indicated by broken skulls, broken limbs, or weapons or parts of weapons embedded in the skeletons, thirdly, an area in which are found remains of ornaments, pottery, weapons, stone implements, etc. How the Lat'te were built is unknown, but in size and in the skill and industry required to build them they are comparable to Stonehenge

THE SCAPEGOAT IN INDIA —Although the custom of using the scapegoat as a means of expelling diseases is extinct or on the verge of extinction in most parts of India, Dr. Sunder Lal Hora has been fortunate enough to come across an example among the Gonds in the Bilaspore district of the Central Provinces. animal stuffed, and with its insignia, is to be exhibited in the Ethnographical Gallery of the Indian Museum, Calcutta. By careful investigation, a full account of the method of procedure was obtained and has been recorded in Journal and Proceedings of the Asiatic Society of Bengal, vol. 21, No. 3. When a disease such as smallpox is raging, the village resorts to the ceremony of Nikasi. A female goat is purchased by public subscription, and is adoined with ornaments usually affixed to the image of a goddess An anna is stuck in the middle of the forehead and near it six yellow spangles A string of yellow lac beads is placed round the horns, to which is attached a peacock's feather standing between the horns Beads of various colours, red and yellow predominating, glass bangles, and coloured threads are also used to ornament the goat. The significance of these rests in the fact that they are the ornaments of a goddess It is clear that in the course of the ceremony the goat becomes the goddess of the disease The disease is removed by the goat being passed on from village to village until she reaches her own temple or is devoured by wild beasts on the way.

EYESIGHT TESTING —The issue of the *Dioptric Bulletin* for September contains the papers read at the International Congress at Oxford in September last, organised by the British Optical Association, and is a volume of about 240 pages. Most of the 32 papers dealt with technical matters, but there were some of general interest dealing with eyesight tests. Dr.

F A Woll of New York gave the results of his tests of the evesight of 552 freshmen entering college in 1926. Of these, only 136 had normal vision, 156 had slight hyperopia, 32 wore glasses for it, and 35 more needed glasses; 122 wore glasses for myopia and 49 others needed glasses. Mr R O. Raphael gave an account of the work done by the Industrial Fatigue Research Board in demonstrating the relation between good sight and industrial efficiency of the workman. As examples he gave cases in which provision of suitable glasses raised the earnings of groups of employees 10, 15, and 27 per cent respectively.

Philippine Fishes.—The Sparoid and Rudder fishes of the Philippines are described by A. W. Herre and H. R. Montalban in the Philippine Journal of Science for August last. Four genera of the Sparidæ and two of the Kyphosidæ are found to occur, whilst the authors add four species of sea-bream to the records for those islands. Keys, accompanied by plates, are given for the identification of all the species, but it should be borne in mind that distinctions based on the colours of the fishes are very slender, and are to be avoided if possible. Members of both families are highly prized as food, and provide a basis for important hand-line fisheries in Japan and Formosa. The various species of sea-bream form one of the main sources of supply for a dried-fish industry carried on at Sitankai, in the Sulu archipelago.

A Thumb Claw in Fowls and Ducks—T Kageyama (Proc Imp. Acad Tokyo, July 1927) records the presence of a claw on the thumb in domestic fowls Out of 131 fowls examined, 111 had the claw on both right and left thumbs, 12 on the right thumb and 3 on the left, while 5 had the rudiment of a claw on both thumbs—Of 14 ducks observed, 12 had a well-developed claw on both right and left thumb. The presence of a claw is not therefore of rare occurrence, as is often supposed.

Size and Colour Inheritance in Impatiens—The inheritance of a character not frequently met with in flowers, namely, difference in size of certain petals, has been studied by B. S. Bedell, of the Imperial College of Tropical Agriculture, Trinidad (Gardeners' Chronicle, Oct 29, 1927) The species investigated was Impatiens balsamifera, and the characters selected were the size of the posterior lateral petal and the colour of the flower. The petal in question may be quite small, simply a small lobe overlapping the anterior petal, or it may be large or equal in size to the anterior. It has been found that 'smallness' and 'largeness' constitute a simple Mendelian pair of characters, with 'smallness' dominant and 'largeness' recessive, the characters segligating after crossing in approximately typical Mendelian proportions. In the case of colour, it has been shown that in the varieties dealt with there is a colour factor, in the absence of which the flower and stem become white and green respectively. If it is associated with a blueing factor, the flower will be purple, or if with a reddening factor, the flower will be scarlet, if both are present, in addition to the colour factor, the flower will be magenta.

Virus Diseases.—Probably the most important line of endeavour in plant pathology research at the present time is connected with investigations of virus diseases, which have also stimulated some interest in medical research circles on account of a possible analogy with cancer. The Agricultural Experiment

Station of the Michigan State College has just issued Bulletin No 80, on the virus diseases of raspberries, by C. W. Bennett. Five distinct virus diseases have been distinguished, and considerable experimental work has been done in investigating the aphids responsible for transmitting the diseases from plant to plant. Specimens of Aphis rubiphila were able to communicate the infection after being away from contact with infected plants for torty-eight hours. There is also considerable evidence to show that the same species can carry the virus and infect healthy plants after a period of more than three weeks. No evidence was obtained to indicate the presence of virus in the egg stage of the aphis. Girdling experiments on infected plants showed that virus failed to pass the girdled part, indicating that the virus moves in some part of the bark. The sieve-tubes would seem to be the most natural channels for such movement, which showed some evidence of a correlation with food translocation. The movement of virus through a plant seemed relatively slow, and some of the canes of diseased plants remained healthy until the spring following infection. Wide varietal range of susceptibility, apparent immunity and tolerance in relation to the different virus diseases, were found in the raspberry group

THE PHOTOGRAPHIC ACTION OF H-RAYS -Some applications of this method for studying H-particles are described by M. Blau in Communication No. 208 from the Institut fur Radiumforschung in Vienna. The best results were obtained with dental X-ray films, which after exposure at a large angle of incidence to protons from paraffin, showed well-defined linear sets of discrete spots, which were somewhat more widely spaced than if they had been produced by a-particles. The emulsion was sensitive to a number of the particles the residual range of which in air was less than 2 cm. The results with disintegration protons were less satisfactory, and were qualitative rather than quantitative, but a number of records were made with retrograde particles, which, it is claimed, support the general contentions of the Vienna school, and show in particular that the carbon nucleus can be disrupted.

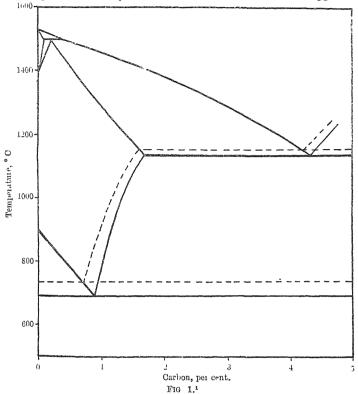

THE ELECTRON THEORY OF METALS -In an article in Die Naturwissenschaften of Oct. 14, Prof. A Sommerfeld points out that if Fermi's system of quantum statistics is adopted, the free electrons in a metal at room temperature are equivalent, so far as departure from classical theory is concerned, to a molecular gas which is almost at the absolute zero, and that this hypothesis leads to important modifications of the expressions for several of the properties of metals. conspicuous success of the application of this principle is the deduction of the Wiedemann-Franz relation between the electrical and thermal conductivities, with a factor of proportionality which is much closer to that found experimentally than that predicted by Prof. Lorentz for a Maxwellian distribution of energy. The constants of the thermo-electric circuit also prove to be at least of the right order of magnitude, although the formulæ from which they are obtained are very different from those used perviously, but the Volta series is the reverse of that found in practice. Prof. Sommerfeld considers that the weak point in his theory is the assumption—which is also inherent in most of the older work—that the mean free path is a purely geometrical quantity, determined by the space-lattice, but that in spite of this, the application of the new system of statistics has removed a number of discrepancies between theory and experiment, and should be capable of extension to other phenomena, amongst which he includes tentatively ferromagnetism.

PERMALLOY SUBMARINE CABLES. The use of permalloy, a material of high magnetic permeability, as a covering for the copper conductor of a long submarme cable has multiplied the signal speed attainable nearly ten times. In a paper by Mr. J. Gilbert, published ... m the Bell System Technical Journal for July, the results of laboratory experiments to determine the constants' of the lines prior to laying are described. When it is remembered that the actual cable when laid is subjected to a hydrostatic pressure which sometimes exceeds 10,000 pounds per square mch, it will be evident that measurements of the characteristics of the cable when subjected to this stress can only be made in the laboratory on a very small scale. The properties of the dielectric are affected by the pressure, and it is probable that the permeability of the permalloy is also affected. It is found that measurements of the capacity of the laid cable and the damping of the signals and their time of propagation, supplemented with laboratory measurements of eddy current losses, are sufficient to determine the four constants assumed in the mathematical theory, provided we know the relative resistances of the return paths for the signals in the sea water and in the armouring of the cable respectively. The experimental results make it highly probable that the electrical conductivity of the earth at the bottom of the sea is very much smaller than that of sea water Experiments on three laid cables are described, and the methods of computing their constants are discussed.

INCREASING THE LIFT OF AN AEROFOIL.—The work recently described by Prandtl before the Royal Aeronautical Society has apparently stimulated research of a very practical kind at Government research stations in Great Britain. Prandtl has shown that the state of flow behind a body moving in a fluid may undergo enormous change by withdrawing some of the fluid in the near of or on the boundary of the body when turbulence is setting in. In aerotoils it is very important if possible to increase the maximum lift coefficient This has been effected to some extent by the use of the Handley Page slot, whereby stalling is delayed to a much larger angle of incidence, and hence increased lift is obtained. It is known that the stall occurs when the stream lines break away from the upper surface of the aerofoil as a result of a reduction in energy under the viscous forces. In R. and M. No. 1100, on "Wind Tunnel Experiments on the Effect on the Maximum Lift of withdrawing and discharging Air from the Upper Surface of an Aerofoil," by Perring and Douglas (London: H M. Stationery Office, 1927. 6d. net), some experiments on an aerotoil are described where the air is discharged or removed from its upper surface. The aerofoil was fitted with slots along its span and provided with a means for measuring lift while air was discharged or withdrawn through these slots. By discharging air tangentically along the upper surface from a point near the leading edge a considerable increase in maximum lift is obtained, while a steady improvement occurred as the quantity of air discharged was increased. Similar results were obtained when the air was discharged into the aerofoil. The effect was dependent principally on the quantity of air concerned, and only to a minor extent on its velocity through the slot. The position and shape of the slot appear in this investigation to be very important, and better results are likely to be obtained in the near future. The importance of this investigation can scarcely be overestimated and if successful, it provides a striking illustration of the application of model hydro-dynanuc experiments to full scale practice.

#### A New Theory of the Cast Irons.

OF the papers submitted to the Iron and Steel Institute at its recent meeting on Sept 20-22 in Glasgow, one at any rate stands out as a contribu-

suggested that the carbide equilibrium is the stable one. Prof Hanson has now considered the results which would follow from a change over from one system to the other as the temperature is varied. If, for example, graphite is the stable form at temperatures up to, say, 1000° C and carbide stable at higher ones, then the dotted line separating the austenitic phase from one in which free graphite or carbide also exists must cross the ordinary cementite line at that temperature, and thence onwards up to the solidus will lie to the right. As a result, a type of diagram similar to that of Fig. 2 will be found. It is, perhaps, right to point out that although the advance copy of Prof.

the dotted lines in the figure represent, therefore, the

graphite equilibrium. Alternatively, Rosenham has

forward by Honda

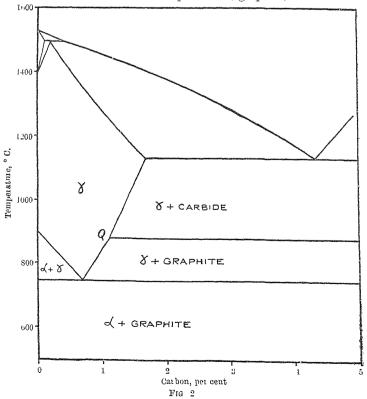

The normal cast irons and steels are not, however, pure binary alloys and represent sections through at least a ternary model, silicon being for the present purpose the most important addition. Where the amount of this is insufficient to cause the introduction of a new phase its effects upon a diagram such as Fig 2 are considered, and in the light of the experimental evidence obtained, it is shown that these results can be represented completely by a diagram of the form of Fig 3 and by no other

Hanson's paper does not refer to the fact, some such suggestion has already been put

It is yet too early to say how completely the new hypothesis and diagram fit in with all the established facts regarding the relationships of iron, graphite, and carbide.

tion of far more than usual interest. Carbon may exist in the unhardened irons and steels in the free state, in all probability as graphite, or combined with the iron as the carbide  $Fe_3C$  In the steels the latter form is almost invariably the one present, while in the grey irons it is graphite. The relationship of these two forms has been by no means cleared up, though in general it has been assumed that in the stable condition the solid material would contain the carbon in the graphitic form, the carbide being a metastable constituent This is represented in thermal equilibrium diagrams by super-posing the one for the graphitic metal upon that for alloys containing carbide. This double diagram has been admittedly incomplete and unsatisfactory, and a noteworthy contribution is made to the subject by Prof. D Hanson, who, on both experimental and theoretical grounds, now offers a single diagram in which phase fields are deliminated in which both types of carbon are to be found.

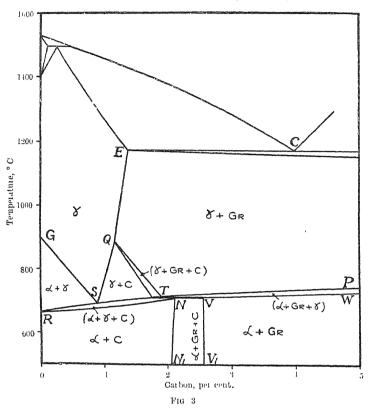

The most generally accepted diagram, that in which both the iron-carbon and the iron carbide equilibria are independently shown suggested by Roozeboom, Benedicks, and others, is shown in Fig 1.1 Graphite is represented as the stable phase at all temperatures below the solidus, and

<sup>1</sup> This and the other illustrations are reproduced by courtesy of the Iron and Steel Institute.

No. 3032, Vol. 120]

Certain facts regarding the presence of graphite in carbon steels, particularly those which have been cold worked, do not appear to be altogether in accord with the new ideas, but this is probably merely a question of the exact position of the limits of the phase fields. To Dr. Hanson the credit is due for opening up

possibly an almost undreamed-of simplification of existing notions concerning these hitherto very complicated materials.

F. C. T.

#### Aeronautical Research in Great Britain.1

THE steady advance which has shown itself in all aspects of aeronautical research since the inception of the Aeronautical Research Committee is marked by the appearance of the report for the year 1926-27. It is a standing tribute to the work which may be done by a team of steady, earnest workers marshalled in their activities to a definite end.

It is difficult to separate out the investigations by placing them in separate categories, for a considerable amount is of a general nature and overlaps into several fields. Broadly speaking, however, the work of investigation deals with aerodynamics, airships, engines, and materials, but each of these is itself a composite group.

There are numerous papers dealing with the measurement of performances of aeroplanes, especially with the newer method introduced at Martlesham, by Lieut. Capon. In air-screws the impact of the Lanchester-Prandtl theory of fluid motion makes itself apparent in a series of papers by Glauert and Lock. Here a difficult subject is being pushed

1 "Report of the Aeronautical Research Committee for the [year 1926-27." (London: H.M. Stationery Office, 1927) 23. net.

several stages further—A problem to which members of the research staffs concerned have devoted close study is that of generation and avoidance of spinning in aeroplanes, and this year sees the production of a considerable volume by Gates and Biyant, where the whole of the subject is discussed in the form of a

special monograph. For those who strive to retain contact with this rapidly developing subject, this new departure by the Aeronautical Research Committee of summarising in this form at stages the work which has been accomplished is to be highly commended. The further development of the subject by the complete representation of a spin in the wind tunnel is progressing. It is hoped that this work, in conjunction with detailed records of the motion of spinning aeroplanes taken at the R.A.E., will cluedate those points which are still obscure.

The suspicion that recent aeroplane accidents have been associated with wing flutter has constrained the Committee to set up a special section for the investigation of this problem. At the National Physical Laboratory, Teddington, it is now possible to demonstrate at will various types of flutter that have been experienced in flight. The problem of determining the aerodynamic characteristics of aircraft during flutter is still the subject of investigation, but certain recommendations for the avoidance of dangerous vibrations in future aircraft have already been put forward, and modifications to existing types of aeroplanes exhibiting this phenomenon have been suggested with the view of its suppression.

A new departure is seen in the development of a tailless aeroplane by Captain Hill While various experimental difficulties had been experienced with the

lightly loaded aeroplane of this type, these have now been overcome, and some development may be looked to in the near future. It is reported that this aeroplane is quite stable and controllable in flight at large angles of meidence.

On the purely scientific side, some interesting experiments are detailed on the two-dimensional airflow behind a flat plate inclined at various angles. Studies are made of the frequency and velocity with which the individual vortices pass down stream and measurements are made of vortex strength. The results show a very fair agreement with Karman's formula, the longitudinal spacing of the vortices remaining constant for a distance of several plate widths down wind.

Meanwhile, at Cambridge, an experimental water-tank has been erected, in which two-dimensional bodies are towed through water. By this means a Reynolds' number of approximately  $10^4$  has been obtained, and it is hoped to produce results shortly with numbers so high as  $5\times 10^5$ . Thus an approach is being made to the corresponding number for normal flight, namely,  $3\times 10^6$ .

While stress has here been laid on the aerodynamic side of this year's report, this is done merely to indicate the kind of advance which shows itself in all the other sections under the influence of systematic and co-ordinated research work. As an experiment in organised research, the Aeronautical Research Committee may in many respects be taken as a model.

#### University and Educational Intelligence.

Cambridge.—Mr W. Dawson, Gonville and Caius College, has been re-appointed reader in forestry Mr. T. M. Harris, Christ's College, has been appointed demonstrator in botany.

A COURSE of twelve Swiney lectures on The Geological History of Scotland will be given by Dr. R Campbell in the lecture theatre of the Imperial College of Science (Royal College of Science), South Kensington, at 5 30, on Dec 12, 14, 16, 19, 21, 23, and Jan 2, 4, 6, 9, 11, and 13 Admission will be free

The following travelling fellowships for women graduates, for the academic year 1928–29, are included among those announced by the British Federation of University Women, Crosby Hall, Cheyne Walk, SW 1, from the secretary of which application forms and regulations may be obtained. The Rose Sidgwick Memorial Fellowship, value £400, for research work in the United States, to a British woman graduate (latest date of application, Feb. 15). An International Junior Fellowship, value £250 (offered by the International Federation of University Women), for research in biological or physical science, or in mathematics (latest date of application, Feb. 15).

It may be remembered that a committee composed of representatives of teaching and industrial bodies and learned institutions was formed in 1925, under the chairmanship of the late Right Hon Loid Emmott, to inquire into the relationship of technical education to other torms of education and to industry and commerce A report embodying some of the chief results of the committee's investigations was discussed at a meeting held in the Regent Street Polytechnic, London, on Nov. 18, under the chairmanship of Sir Robert Blair. The report was approved, and it was agreed that it be submitted to the President of the Board of Education The following deputation was appointed to wait upon the President of the Board of Education in this connexion: Sir Robert Blair, Sir Benjamin Gott, Mr W Prescott (Federation of British Industries), and Mr J. Wickham Murray.

The annual meeting of the Geographical Association will be held at the London School of Economics, Houghton Street, London, W.C.2, on Jan. 4-9 Dr. Vaughan Cornish will deliver his presidential address, "Harmonies in Scenery," on Jan 7; the address will also be broadcast from 2LO by Dr. Vaughan Cornish on Jan. 9 Lectures have been arranged by Dr Marion 1 Newbigin on the geographer and the study of climate (Jan 5), Sir John Russell on Palestine and its agricultural possibilities (Jan. 5), Prof. Rodwell Jones on the prairie provinces of Canada (Jan 6), and Sir E. Humphrey Leggett on economics and administration in British East Africa (Jan. 7). On Sunday, Jan. 8, the Rev. Canon C. S. Woodward will preach at Evensong in Westminster Abbey on "International Relations in the light of Geographical Science." Visits to the Imperial Institute and to demonstrations of educational films are being arranged, and a publishers' exhibition will be open on Jan 5-7. All communications regarding the meeting should be addressed to the honorary secretary, Prof. H. J. Fleure, 11 Marme Terrace, Aberystwyth.

#### Calendar of Discovery and Invention.

December 11, 1691.—Prior to the use of steam for pumping engines, experiments were made on the employment of gunpowder for the production of motive power. In the "Calendar of State Papers" is the following entry "Decr 11th, 1691—Wariant for a grant to Sir Samuel Morland of the sole use for 14 years of his invention for raising water out of pits, etc., to a reasonable height, by the force of powder and air conjointly."

December 11, 1863.—In 1838 two English chemists, Dyar and Hemming, patented a process for producing carbonate of soda by the action of ammonium bicarbonate upon sodium chloride, but all attempts to manufacture by this process failed until the Belgian chemist. Ernest Solvay, devised modifications in it which were patented by him in England on Dec. 11, 1863. With his brother Alfred, Solvay started works near Brussels in 1866. In 1873 a hience was granted to Brunner and Mond, and by 1914 there were throughout the world 23 separate works engaged in the Solvay ammonia-soda process capable of producing nearly 2,000,000 tons of soda-ash annually.

December 12, 1901.—It was on Dec 12, 1901, in a room in a disused barracks on Signal Hill, St Johns, Newfoundland, that Senatore Marconi heard faintly in a telephone the groups of three dots, constituting the morse letter S, transmitted from Poldhu in Cornwall. The detector used was a self-restoring coherer and the aerial a thin wire carried to a height of 400 feet by a kite. One feature of the experiment was that its success disproved the theory then widely held, that the transmission of radio signals over great distances would be impossible owing to the curvature of the earth.

December 14, 1874.—On this day Cornu communicated to the Paris Academy of Sciences the result of his redetermination of the velocity of light. His methods were fundamentally the same as Fizeau's, but his precision was greater

December 15, 1859.—One of the landmarks in the history of the spectroscopic examination of the sun was the memoir read by Kirchhoff to the Berlin Academy of Sciences on Dec 15, 1859, in which he explained the nature of the lines in the solar spectrum

December 15, 1904 —Though attempts were made' from time to time to elect women into the Linnean Society of London, it was always found that the original charter did not permit this being done. A supplemental charter was therefore obtained in April 1904, and the first election of women as fellows took place on Dec. 15 of that year

December 16, 1883.—To Gottlieb Daimler we owe the first high-speed internal combustion engine with high compression, which he patented in Germany on Dec 16, 1883

December 17, 1849 —The well-known form of pressure gauge with the curved tube of elliptical section was invented by the French engineer Bourdon and patented by him on Dec. 17, 1849 —He was led to the invention by observing the motion of the end of a coil of copper pipe when being tested.

December 17, 1903.—The pioneering work of the Wright brothers, leading to the construction of the first practical flying-machine, was spread over the years 1896-1903: and it was on Dec. 17, 1903, on the lonely sandhils at Kitty Hawk, North Carolina, U.S.A., that the brothers made their first flights. Orville Wright flew first for 12 seconds, and the same morning Wilbur Wright flew for 59 seconds

#### Societies and Academies.

#### LONDON

Geological Society, Nov. 16 - W D. Lang, L F Spath, L. R. Cox, and Helen Marguerite Muir-Wood. The belemnite-marks of Charmouth, a series in the Lias of the Dorset coast—Pale marls, lying in the Lias above beds with Echioceras and below those with Androgynoceras, extend along the Dorset coast for about four miles Forming the third, and highest, Lias precipice on Black Ven, they are soon truncated by the eastern slope of that clift, but reappear eastwards to form the second precipice at the western end of Stonebarrow Cliff. They descend to the beach at Westhay Clift, and form a gentle syncline, so that the lowest beds are carried beneath the tide opposite Westhay Water They rise for a short distance on Ridge Cliff, but soon are thrown down and out of sight by the Ridge Fault. Thereafter only the highest beds of the belemnite-marks are seen. The marks contain few beds in which ammonites are well preserved. Ammonite-remains, however, are to be found throughout, and although the preservation is often poor, a sequence has been established. Except at a few horizons, belemnites are not common below the belemmite-marls, but they abound in the marls, and, if the outstanding forms are carefully collected, they show, like the ammonites, limited ranges and a crowded sequence. The gastropod molluses are few in number of species and not suitable for showing zonal distribution. The same may be said of the lamellibranchs. The ammonites are only of local value in establishing a sequence.

Royal Meteorological Society, Nov. 16.- (' E. P. Brooks. The influence of torests on rainfall and run off. Of the water vapour which is condensed as rainfall over the land, about two-thirds is provided by evaporation over the oceans, and the remaining third by evaporation and transpiration over the land. The latter contribution is made up of the evaporation of rainfall intercepted by foliage, evaporation from the soil, and transpiration. As percentages of an average rainfall of 30 mehes a year, the amounts are (a) for forests: interception 15, evaporation from soil 7, transpiration 25; (b) for crops evaporation from soil 17, transpiration 37; (c) for bare soil: evaporation 30 per cent. Thus replacement of forests by crops tends to mcrease the supply of moisture to the air, and therefore the general rainfall slightly; replacement by bare soil would decrease the general ramfall slightly Replacement of forests by crops would decrease the run-off by 15 per cent, and make it less regular; replacement by bare soil would increase the run-off but would make it highly irregular. A forest 30 teet high adds about 30 feet to the effective height of the ground, and this should merease the local orographical ramfall by one or two per cent At Mauritius, deforestation has resulted in a decrease by two or three per cent, while in Sweden, Germany and India the rainfall at forest stations is about one per cent. greater than that at neighbouring stations in the open. Under average conditions the total effect of fog and dew is slight.—C K M. Douglas. The secondary depression on the night of January 28-29, 1927. The discontinuities associated with this intense and deepening secondary depression were examined in detail by means of autographic records at a number of stations. About 70 miles behind the first cold front there was a 'dry front,' with a rise of temperature and sharp fall of relative humidity, separating air kept cold and damp by the rain, and air behind the rain area which had been warmed at

the dry administerate when it descended. Near the centre of the secondary depression a 'secondary warm sector' was developed after the original warm sector was 'occluded,' re displaced entirely from the lower layers of the atmosphere E. Kidson. The circulation of the atmosphere over Melbourne. It is possible to obtain estimates of wind velocity at high levels by means of nephoscope observations with accuracy sufficient at least for most purposes. No other means is at present available for securing a comparable amount of data for the same levels in a clunate such as that of Melbourne. These upper winds are freed from the purely local effects, though large-scale local effects are still of great importance.

Linnean Society, Nov. 17--N. E Brown The South African species of Iridacea in Thunberg's herbarum Carl Pehr Thunberg was born in 1713, and in due course became a pupil of Linné, and afterwards professor of botany at Upsala. He sailed from Europe on Dec. 30, 1771, and landed at Cape Town on April 17, 1772, the journey occupying fifteen weeks. Thunberg stayed in South Africa nearly three years, and sailed to Java on Mar. 2, 1775 During his stay he made three extensive journeys, and in two of them was accompanied by Francis Masson, who was sent to collect living plants for the Royal Botanic Gardens at Kew. Thunberg sent or brought back from the Cape a large collection of dried plants and described them in numerous separate pamphlets and in his "Prodromus Plantarum Capensium" and "Flora Capensis."—A. W Exell: Some hybrids of Cotoncaster frigida Wall. Various hybrids of *C. fragida* Wall, have arisen at the Bagshot nurseries of Messrs-Waterer, Sons and Crisp. One or two of these are of considerable horticultural value. George Matthai. Exhibition of photographs and drawings of recent Meandroid Astreid corals. The photographs represent nearly all the known species of recent Meandroid Astraids, and refer to material collected from the Indo-Pacific (including the Red Sea) and the Atlantic regions as well as to type-specimens m the European and American museums. They were taken with the view of showing the probable limits of \(^4\) genera and species, the range of skeletal variation within each species, the appearance of the soft parts and of stages in the growth of colonies, and illustrate, for the first time, many of the types of previous authors The drawings are illustrative of the histology of polyps after decalcification, and have been made from serial sections. The plates will accompany a forthcoming monograph in which a revised classification of the group is made from a comparative study of their hard and soft parts and of existing type-specimens.

#### CAMBRIDGE.

Philosophical Society, Oct. 29.—4. C. Steward: On the lens interferometer. The lens interferometer offers a method of examining the aberrations of an optical system by means of the interference tringes given by a wave of light which has passed through the system—which therefore is distorted by the aberrations impressed upon it—and an 'ideal' wave which would be given by a 'perfect' system. An examination is made of the various types of fringes to be expected in the presence of the different geometrical aberrations of the symmetrical optical system. The basis of the investigation is an 'aberration function,' previously introduced, associated with the characteristic function of Hamilton. This aberration function sums up in itself all the geometrical aberrations of the optical system and depends upon these aberrations alone.—J. A. Gaunt and W. H. M'Crea: The emission of radiation by a quadripole electric moment on the quantum mechanical.

theory of dispersion is adapted to calculate the radiation from the quadripole moment of a system applied to the quadripole radiation of a Planck oscillator ( $\Delta n = 2$ ) and to the case of a rotating rigid homopolar diatomic molecule—G. H. Aston. The amount of energy emitted in the  $\gamma$ -ray form by radium E A method of finding the order of magnitude of the small amount of energy emitted in the  $\gamma$ -ray form by radium E is given. The method involves a comparison of the ionisations of the  $\gamma$ -rays of radium E. radium B, and radium C. The energy is also estimated in another manner, and the two methods agree in showing that the  $\gamma$ -ray energy is of the order of I per cent. of the  $\beta$ -ray energy, i.e. about 3000 volts per atom disintegrating Only one  $\gamma$ -ray quantum is emitted in about thirty disintegrations, and it is suggested that this  $\gamma$ -radiation has a continuous spectrum —W H M'Crea: (1) The specific heat of water vapour and the theory of the dissociation of water vapour at high temperatures. The elementary (quantum) theory of the specific heat together with dissociation accounts quite satisfactorily for the observed specific heat of steam. The dissociation theory is applied in such a manner that it also checks the observed values of the dissociation and enables one to estimate certain molecular constants from them. The range of temperature considered is about 100° C.–2000° C (2) The specific heat of carbon dioxide and the form of the CO2 molecule Neither the linear nor the triangular model hitherto given for the carbon dioxide molecule accounts properly for the observed specific heat curve. A hypothesis on which the molecule changes from the first to the second form when a certain vibration becomes excited is suggested. It gives better agreement for the specific heat and seems to explain some anomalies of the band spectrum. The effect of the interaction between vibration and rotation on the specific heat at high temperatures is considered.

#### CALCUTTA.

Asiatic Society of Bengal, Nov. 7.—H. Bruce Hannah: Indian origins. It is suggested that the old Dasyus of Sapta Sindhavah introduced Nature worship into northern India in Vedic times; that they became the Brahmans of Kuruland; that Taxila was a city of theirs; and that the 'finds' recently made at Harappa and Mohenjo-Daro were Dasyuan and have nothing to do with Sumer.—W. Ivanow: Notes on Khorasanı Kurdish.—Mrs. C de Beauvoir Stocks: The Khyber Hazari. This tribe inhabits the Lolab valley in Kashmir, but their original home is in the Hazara district to the east of Afghanistan.— R. D. Banerji. The Indian affinities of Ainu potteries. Three types of Ainu pottery discovered among the shell mounds of the sea coast of north-eastern Japan and preserved in the Museum Shoshu-Kan, show a marked resemblance to Indian prehistoric pottery of the Copper Age. The first of these is a suspension vessel, numerous examples of which have been discovered in Baluchistan, Mohenjo-Daro and Harappa. The second is a 'wine cooler.' Such vessels with handles have been discovered in Japan and Baluchistan and without handles in Taxila and Baluchistan. The third type is a bird-shaped vase, numerous examples of which have been discovered at Mohenjo-Daro and Harappa. It resembles the famous dove-vase from

Knossos.—D. N. Majumdar · A few types of Ho Songs—C. J. George: South Indian Aphididae The results of a preliminary survey of the aphid fauna of South India, with special reference to the species found in the neighbourhood of Combatore, is given. This is a first step towards devising control measures against plant lice in those parts.

#### Rome.

Royal Academy of the Lincei: Communications received during the vacation —J Hadamard and E. Landau · Entire functions of finite species —C. Foà · The neurochemical mechanism of vagal inhibition in the heart of mammifers. Further experiments show that, in the heart of mammifers, vagal inhibition is accompanied by liberation of a substance of inhibiting effect, and that this is probably destroyed rapidly in the texture of the myocardium where it is produced and does not pass into the coronary reflux cucuit unless the conditions of permeability of the cardiac fibre are altered, for example, by sprinkling the isolated heart with Ringer-Locke solution.—A. Russo · Attenuation of the sexual power of the impure gametes which accomplish the second accessory conjugation in Cryptochilum echini —L. A. Herrera: Imitation of organised forms by means of sodium stearate. Further experiments, with ordinary petrol and sodium stearate, confirm the importance of the fatty acids in morphogenesis -R. Caccioppoli: Multilmear and higher degree functionals.—G. Krall: Infinitesimal variation of Green's functions relative to pluri-connected plane fields.—R Mazet: Complements to a note on the oscillation of a liquid in communicating vessels.—G. Thomsen. The rotation of the earth in relativistic mechanics.—A. Merola: Photometric observations of the new variable in the constellation Auriga.—M Baruzzi: Periodic courses of the mean diurnal temperature at Modena—F. Eredia: The resultant direction of the wind at various altitudes deduced from observations of pilot balloons at Vigna di Valle (Bracciano).-F. Rasetti: The intensity of a prohibited potassium line. Investigation of the anomalous dispersion by Puccianti's method gives for the doublet  $4^2S - 3^2D$ ,  $\lambda 4642$ , of the potassium spectrum a number of dispersion electrons one million times less than for the first doublet of the principal spectral series, λ7665, 7699.—A. Ferrari: Crystalline structure of the bivalent chlorides. Anhydrous cobalt and nickel chlorides. These chlorides exhibit the same structure as magnesium chloride, being rhombohedral and pseudo-cubic. The rhombohedra constituting the elementary cells contain 16 molecules and have for a the following values: MgCl<sub>2</sub>, 10·16; CoCl<sub>2</sub>, 10·02; NıCl<sub>2</sub>, 10·00 A. The calculated densities are respectively 2·41, 3·43, and 3·45—L. Mascarelli: Contribution to the knowledge of diphenyl and its derivatives. Interpretation of the plane of the plane of the contribution of the contribution of the contribution. derivatives. Interpretation of the phenomena of optical isomerism. Of various diphenyl derivatives examined, only 2: 2'-diamino-6: 6'-dimethyldiphenyl appears to be resolvable into optical antipodes. This compound was obtained by treating 2-iodo-3-nitro-toluene with powdered copper and reducing the resultant 2: 2'-dinitro-6: 6'-dimethyldiphenyl. Under the action of d-tartaric acid it gives a sparingly soluble salt which is converted by ammonia into a lævorotatory isomeride of the original compound.—A. Desio: The Miocene molluscs of Porto Bardia and of the oasis of Giarabub.—M. Piazza: The presence of scorodite in certain tungsten minerals of Portugal.— E. Seren: Investigations on the chromatophores of the cephalopods. Experiments on Octopus vulgaris, Eledone moschata, Loligo vulgaris, Sepia officinalis, Sepiola elegans, etc., show that, with gradual heating, a certain exaltation of the pulsatory activity of the chromatophores often appears between 25° and 30°, this being followed, at 37°-39°, by a general and reversible expansion. On the other hand, on cooling, complete retraction of the chromatophores is observed between 10° and 5°, and evident diminution of the electrical excitability below 5°. The chromatophores exhibit only slight sensitiveness to variations of the osmotic pressure. As regards the influence of various cations, both the alkali metals and those of the alkaline earths have a contracting effect; with the former, this is greatest for potassium and least for sodium, and with the latter, greatest for barium and least for magnesium.—G. Cotronei Time of development of the humoral-nervous correlations. Investigations on amphibia

#### SYDNEY.

Linnean Society of New South Wales, Aug. 31 .-J. R. Malloch. Notes on Australian Diptera (12). This part deals with the family Tachinidæ. new genera and four new species are described. Keys to genera and species are given with many useful notes.—I M. Mackerras: Notes on Australian mosquitoes (Diptera, Culicidæ). Part 2. The zoogeography of the subgenus Ochlerotatus with notes on the species. In this part, evidence is brought forward to support the opinion that both groups of this subgenus of Aedes colonised Australia from South America, one entering this country from the north and the other from the south. A key to adult females is given and the status of the various species is discussed. One species and one variety are described as new.—A. G Hamilton. The xerophytic structure of the leaf in the Australian Proteaceæ. Part I. The author gives a general account of the methods adopted by the Proteaceæ to lessen transpiration, and points out that several recognised devices are not found in the order, as leaflessness, bloom, wax or varnish, hygroscopic salts, and ethereal oils Hairiness, too, is not developed to the extent it is in the South African Leucadendron, although many of the Grevilleas and Banksias have densely hairy undersides to the leaves The conditions leading to xerophylly are discussed, and the view expressed that the main factor is the edaphic conditions. From the fact that favourable conditions do not lead towards the mesophytic form, it is surmised that the xerophytic characters have been so long fixed that no alteration is possible. The structure of the flat-leaved Hakeas is then described, several remarkable modifications being noted. One of the most striking features is the enormous development of sclerenchyma (columnar, detached masses, and fibrous).—G. A. Waterhouse: Australian Hesperudæ. Part 1. Notes and new Australian Hesperudæ. Part 1. Notes and new subspecies. In this paper an alteration of the sequence of the genera in the subfamily Trapezitinæ is given, a new species allied to Hesperilla crypsargyra is described and figured, new subspecies of H. donnysa and H. chrysotricha, and the hitherto unknown female of Toxidia crypsigramma are described and figured.

Royal Society of New South Wales, Oct. 5.—R. H. Cambage: The vertical growth of trees (2). Nails were placed one foot apart in young trees of various species of Eucalyptus, Angophora, Acacia, and Grevillea From four to eleven nails were inserted, and though some trees increased their length by 50 per cent. in five years, and one by 160 per cent in one year, there was practically no extension of the stem up to the highest nail, but the trees grew from the summit or growing-point.

## Royal Society Publications and Meetings.

In his presidential address to the Royal Society on Nov. 30, Sir Ernest Rutherford referred to certain defects in the publications and in the meetings of the Society It appears that the scientific communications made to the Society are important enough to demand publication, and so numerous that the Proceedings have considerably increased in volume, at any rate in the Physical or 'A' series. The sales, however, though they too have increased, still remain insufficient to cover the cost of printing. Thus the defect of the publications is formulated by the president as a lack of funds, and he appeals for further endowment.

It should be remembered that very many of the Society's publications are sent out partly as gifts, partly in exchange for other publications, and the value of the latter at least should be set against the pecuniary deficit But, making all allowances, we conclude that the Royal Society has no more success with its publications than have many other scientific societies. From numerous quarters the complaint arises that papers cannot be published, that societies cannot find the money, or that editors and authors have to pay from their own pockets. On the other hand, we see some of our societies in an apparently flourishing condition and many scientific journals produced here in a manner that does not suggest lack of public support, while the number of new scientific periodicals that has sprung up in Germany since the War can scarcely be due to an excess of altruism on the part of German publishers. We can see only two possible reasons for this curious contrast. the failures must be due either to a lack of business management or to the simple fact that the goods are not wanted In these days the appreciation of even the most abstract science is so widespread, and the number of scientific workers and institutions so enormously increased, that there certainly ought to be a demand for the publications of the premier scientific society, so long as they are reasonably up to standard. If this be conceded, an inquiry into business methods becomes the natural suggestion.

If, however, the papers presented to the Royal Society do not appeal strongly enough to the outside world when published, still less do they appeal to the fellows when they come up for reading and discussion. The president's remarks on this subject are almost pathetic. He says: "While special lectures and discussions, and some of the ordinary meetings, are in general well attended, there are occasions when important and interesting

papers are read before a very small audience Quite apart from the painful impression left on the presiding officers, the sparse attendance has inevitably a discouraging effect on the reader of the paper, particularly, as is often the case, if he has come from a distance and spent much time and trouble in order to present the subject matter of his paper in an interesting way "

Sir Ernest merely repeats a very old complaint when he speaks of the "sparse attendance" and "discouraging" lack of interest extent this is a natural consequence of the constitution of the Royal Society It differs from the other learned societies of the metropolis in two points · its members represent all branches of science, and each member is a distinguished specialist in his own branch. Now it is generally, if not universally, true that the more a man knows of one subject, the less does he know of other subjects The number of fellows capable of appreciating an advanced paper on any special theme is necessarily a small minority. The reader of a paper to the Zoological or Geological Society may be sure of an audience of fifty or sixty (as a rule the numbers are far more), and the discussions are only checked by want of time At the Royal Society the same reader would get about one-tenth, simply because he has far less than one-tenth the number of that outside visitors would be welcome, one reply is that few besides those who have retired from active work can attend a meeting so early as 4.30 P.M.

In view of the necessary composition of any probable audience, there are two improvements still feasible. First of all, the author should remember that if in any society his audience must ex hypothesi know less about his subject than he does himself, in the Royal Society the general level of knowledge will be far lower. The less knowledge he assumes in his audience the more successful will his exposition be. "I know that I know, but all the same tell me as if I didn't know." Lack of knowledge does not, of course, imply lack of intelligence It is generally the youngest authors that are most difficult to follow, and a little friendly advice from the officers might induce them to condescend to the level of an F.R.S. In a society hke the Royal, even more than in other societies, the audience is less interested in detail than in the general conclusion, and above all the reader should bring out the relation of his bit of work to the broad concepts of the science. If any readers find that they have too little to say in these aspects, they may perhaps withdraw their claims for time and printer's ink

This leads to the subject matter. It is perhaps, mevitable that the meetings, and still more the Proceedings, should have become a convenient platform for the pupils of fellows of the Society who happen to be distinguished professors The work produced is doubtless valuable but is it of such prime importance as to attract a number of busy men of mature age to Burlington House on a winter afternoon? However this may be, there is no doubt that the Society has turned into a publishing body for a limited number of the physical sciences Indeed, Sir Ernest Rutherford seems almost to glory in the fact, much as Sir Charles Sherrington might take pride in the thought that series B' consists so disproportionately of physiological papers The Royal Society may be performing a charitable act in publishing work that has no other outlet, and yet this does not seem to be quite the proper function of a leading, co-ordinating, organising body. Let it publish these contributions if nobody objects, but there is no necessity for them to be read, even at present a considerable proportion of the papers is taken as read

Sir Ernest Rutherford thinks that the meetings would be better if only more fellows would attend. He seems to us to over-estimate the number of those having special knowledge of selected subject matter, and it may be inquired whether this specialisation of the meetings is really on the right The Royal Society is the one place where students in all the sciences can meet, and its gatherings should make the most of this physicist can help the biologist, the chemist can help the geologist. The subjects of discussion should be such as call for this many-sided help and criticism, or they should be of such broad and general nature so as to transcend the limits of specialisation After all, the average fellow of the Royal Society does wish to learn something of the researches of the other fellows; he only asks that they should present their results in a form intelligible to him.

There is far more promise in the president's invitation to fellows to give demonstrations before the meeting. Informal talks on exhibits have successfully brightened the meetings of other societies, and are more likely to loosen the tongues of authorities with a reputation to lose, especially when combined with tea and coffee. Our only feat is that the fellows will succumb to the enhanced attractions of the tea-room and never reach the meeting-room at all.

Anthropology of the Westernmost Orient.

Ritual and Belief in Morocco By Edward Westermarck. In 2 vols Vol 1 Pp xxxii + 608 Vol 2 Pp xvii + 629 (London Macmillan and Co , Ltd , 1926 ) 50s net

PROF WESTERMARCK, by the publication of his first masterpiece in 1891, gained a worldwide reputation as a historian of human marriage and a leading sociologist, a reputation later on increased by his analysis of Moral Ideas," in which he established himself as a psychologist and a philosopher of the first magnitude His merits as a master of inductive method and as a ruthless critic of insidious fallacies, are rivalled only by his power of building sound theories on the bedrock of biology and of our knowledge of human nature fame gained by his theoretical work has ever since eclipsed Westermarck's other equally astonishing achievement as a first-hand student of the savage or barbarous tribes of the Maghrib—the extreme west of the Oriental World Westermarck's great learning somehow suggests the library, and his philosophic detachment and literary charm, a comfortable study in some ancient university closster, and it is difficult to imagine him in the saddle, climbing maccessible mule tracks in the Great Atlas, or as a daring ethnographic explorer of the Rit, braving dangers so real that , at times he had to be declared outside consular ponsibility and the protection of civilised government

No better field-work exists, however, than that of Westermarck in Morocco. It was done with a greater expenditure of care and time than any other specialised anthropological research; it has brought to fruition Westermarck's comprehensive learning and special grasp of sociology: it revealed, his exceptional linguistic talents and his ability to mix with people of other race and culture

Westermarck in the course of more than two decades, between 1898 and 1926, spent altogether the equivalent of seven years among the various Berber and Arab tribes of Morocco. He has investigated native life and culture through the medium of their own language, living among them, frequently forming ties of personal friendship with the hospitable Shereefs and lordly Sheikhs. The present two volumes embody perhaps the most important and attractive results of Westermarck's research. For although his 'Marriage Ceremonies in Morocco' (1914) is as learned and as valuable as the present book, and his numerous monographs are indispensable for the specialist, the strange behefs and rites

of the Berber hillmen and the nomads of the desert will be more interesting to the general reader.

These two volumes, though primarily a model of method and scholarship, read like a novel of Marmaduke Pickthall or the 'Arabian Nights' In fact it is perhaps the best companion and commentary to any oriental classic Take, for example, the jinn, the special race of spiritual beings who constantly play pranks on men and women Any of us who still retain our childish delight in Oriental literature are well acquamted with them, but we have never known their real nature In the present book Westermarck for the first time gives us their genealogy, their natural history, and many wise hints as to how to deal with them origin, their Asiatic and local antecedents, their true sociological nature—contradicting Robertson-Smith's totemic explanation—are given in a special chapter, for Westermarck is always careful to keep theory apart from statement of fact. And then we learn all there is to be known about them from Moroccan folk-lore, the opinions of the Koran, the comments of the learned and the scribe, and above all the stories current among the people This popular belief impresses us with its freshness and imaginative power, with the flavour of the wonderful and miraculous, which prove that the Thousand and One Nights are not yet at an end, unless they be extinguished by the cold light of civilisation recently poured into Westermarck's Morocco by machine gun and aeroplane though these beliefs will undoubtedly soon die, their ghosts will remain in the stories preserved for These stories show us jmn conus in this book sorting with pedlars in the market-place, leading young scribes astray and entering into love intrigues with man or woman—for there are female as well as male junn The spirits become so ubiquitous that we are glad to find in a special chapter exact prophylactic measures against them and remedies for the troubles which they cause.

The long chapter on the evil eye appeals no less to the antiquarian's imagination than to the interest of the sociologist. One of the oldest superstitions of the Mediterranean basin which still survives in the behaviour of civilised man, whether of Latin, Berber or Semitic race, is here described again with a fullness of detail and theoretical might which defies comparison. A wealth of descriptive data, collected at first hand, is given, and then a comparative treatment of the problem, an analysis of the belief, and a number of interesting sidelights on its cultural influences. A description of the imprint of the evil eye upon decorative art,

given with many interesting illustrations, will remain among one of the most illuminating contributions to comparative folk-lore

The anatomy of swearing and cursing will be of great value to all those interested in the subject There is no doubt that a European will feel stricken by the poverty of his own language, more especially, perhaps, the Anglo-Saxon, whose repertoire, since the good days of Shakespeare and the buccaneers, has been gradually depleted by puritanic superstition and mid-Victorian prudery The dilettante will therefore find impressive data in the long lists and full comments given with scientific calm and candour He might be shocked by finding at the outset such a simple expression as "God damn you," somewhat more elaborated in the explicit "God damn your grandfather and the grandfather of your grandfather, and the grandfather of him who will not curse your grandfather," but by the time he arrives at the end of the chapter he will find these expressions pale and lacking in vigour.

Witchcraft and the practices of transference of evil give us a good insight into native belief, with its raw flavour of savagery mingled with certain dramatic reminiscences of medieval Europe. The beliefs and customs referring to animals are narrated, with the repressed but powerful sense of humour so characteristic of Westermarck's style and mind, and make this chapter as amusing as "Esop's Fables", while for the psychology of the relationship between man and beast, important for anthropologists in connexion with totemism, this chapter is of the greatest value. The long and excellent descriptions of the ritual of the dead, the beliefs and practices connected with agriculture, the account of the yearly round, following the solemn festive days of the Mohammedan calendar, can only be mentioned here.

Two subjects have yet to be commented upon as of especial interest to the student of man; one of them is the 'Ar or "transference of conditional curses," a remarkable universal phenomenon first discovered and named by Westermarck. The data given and the interpretation of them illuminate the problem of taboo—the cornerstone of primitive law and primitive religion. Westermarck's comments on the covenant among primitive Semites and his criticism of Robertson Smith will be of value to those interested in the Bible, the Jews, and the learned Scottish historian.

The second subject of outstanding importance is the Moorish doctrine of "holiness" or "blessed virtue," the baraka, which corresponds to the famous mana of the Melanesians, the Iroquian

No. 3033, Vol. 1201

orenda, the Siouan wakan, the Algonquian manitu, and the Malagasy hasina This type of religious conception has been made a pivotal point in modern comparative study of religion, especially through the contributions of Dr Marett of Oxford. Westermarck's account of the baraka far surpasses, in accuracy, thoroughness, and sociological depth, the data we possess from any other area, and it is bound to influence future theories of primitive religion What Westermarck has to say on magic and religion in his introductory chapter ought to be read and considered by all the students of the subject. for it is the result not only of much impartial thought but also of direct experience with a people who, while remaining in barbarism as regards some aspects of culture, were able to produce among themselves individuals singularly well able to analyse their own belief and that of their fellow tribesmen.

To the student of Semitic language and culture, to the scholar interested in the traces of the Carthaginian, Roman, and Hellenistic influence in North-West Africa, to the general anthropologist and the sociologist interested in culture at the level of higher barbarism, these two volumes will be an mexhaustible source of information and delight

B. Malinowski.

## The Story of Radio-Communication.

History of Radio Telegraphy and Telephony-Written and Illustrated by G G Blake xix +425. (London Chapman and Hall, Ltd, 1926.) 25s net.

THE time for writing a history of 'wireless' has scarcely come yet, but it is well that somebody should collect data and sift material for this arduous enterprise Mr. Blake has done this diligently and conscientiously, and the result is a compilation, or more properly speaking a thesaurus, from which future historians may glean with confidence.

The development of wireless has shown a steady evolution enlivened by spurts of discovery. The main dates of these spurts—a biologist might call them 'sports'—are approximately the following

1864. Clerk Maxwell predicts ether waves.

1888. Hertz demonstrates ether waves experimentally

1889. Lodge discovers the coherer and the principle of tuning.

1897. Marconi's long-distance radio-telegraphy.

1907. Lee de Forest invents the triode valve.

1915. First trans-Atlantic radiotelephony.

1920. Broadcasting.

These dates form a useful scaffolding for the historian, but it is surprising how much detail has been almost forgotten. Mr. Blake recalls the fact that it was Mahlon Loomis, an American dentist, who signalled from one mountain top to another by means of kites and atmospheric electricity Another significant anticipation was the transmission of spark signals over a distance of 100 feet by Prof. Elihu Thomson in 1875, twelve years before Hertz. Nor is it generally realised that it was von Bezold who discovered that electrical impulses are reflected from the insulated end of a conductor and are capable of producing nodes and antinodes at different points on the wire. This was in 1870, eighteen years before Hertz, and twenty years before Lecher.

The chapter on detectors recalls many forgotten incidents of wireless development. We find a description of positive point electrolytic detectors of Ferrie, Fessenden, Vreeland, Schloemilch, Shoemaker, and Reich, all of which have been superseded by the various crystal detectors of which Dunwoody's carborundum detector was the first. An interesting chapter is devoted to the photophone and allied methods of signalling by short waves of the order of light waves. Here the author gives full credit to that brilliant German experimenter, Ernst Ruhmer, whose name, by the way, he spells Ruhmer, a very prevalent mistake probably due to over-correction.<sup>1</sup>

Dealing with spark generators of high-frequency currents, the author gives an interesting account of the 'airblast' spark gaps of Lowenstein, Massie, Fleming, Richardson, and Shaw, and the rotary disc dischargers of Lodge and Chambers.

The most valuable chapter of all is the one on the thermionic valve. Here the author's prodigious industry comes into full play. The subject is one which he evidently has much at lneart, and he seems to have followed the development of the valve through all its stages, both practically and theoretically, for we owe to him several beautiful models showing the action of the valve.

The feature which will appeal most strongly to those who wish to find their way through the maze of wireless inventions and discoveries is the list

¹ The linguistic principle of over-correction may be stated as follows: The consciousness of a prevalent fault or omission in using a language leads to correction or replacement in places where it is not justified. The most familiar illustration is the unjustinable reappearance of h's' in southern England, but we may also quote the insertion of non-existent accents in French words; and some writers make the mistake of aspirating consonants (for example, bhoy) or modifying vowels ('same' for 'seem') in places where no Irishman would do so The Germans make similar mistakes Having been told that the final d' of hand is soit instead of hard as in German, they also show a tendency to soften the final consonant in such words as 'boot' and 'book.'

of references, which occupies fifty pages The references are to books, periodicals, and patent specifications, and cover about fifty years.

We are accustomed nowadays to a flood of wireless literature liberally sprinkled with illustrations, which are, in effect, advertisements of certain brands of wireless instruments Mr Blake's book is refreshingly different Most of the two hundred or so illustrations have been drawn by himself, and drawn in a manner which will command the respect of the most advanced electrical draughtsmen Many of these drawings have been prepared to illustrate half-forgotten principles. Any of these might suddenly become of importance. So rapid, and even precipitate, has been wireless progress that many valuable ideas are in danger of being swallowed up and engulfed in the thronging crowd of new things. Mr Blake's book has rescued many a pearl from being thrown on the scrap heap.

E. E F D'A.

# The Borderland of Physical Chemistry and Physiology.

Physikalische Chemie der Zelle und der Gewebe Von Prof. Dr Rudolf Hober Sechste, neubearbeitete Auflage Pp xv1+955 (Leipzig Wilhelm Engelmann, 1926) 42 gold marks.

In his exacting task of elucidating the nature of living processes, the physiologist wisely draws on his colleagues in other branches of science for all the help they can give him. With the aid of the organic chemist, for example, he has already learnt how to isolate, analyse, and synthesise such fundamentally important substances as adrenaline and thyroxine. every day he likewise applies the technique and theories of the organic chemist to further his knowledge of that marvellous sequence of co-ordinated chemical reactions which constitutes metabolism

The relations between the physiologist and physical chemist have been, perhaps, of an even more intimate nature. Physiology, seeing that it consists so largely of interchanges of matter and energy between semi-fluid cells and their fluid environments, offers signal opportunities for the application of theories of solution, mass action, surface chemistry, and so forth. So pressing, indeed, have been the needs of the physiologist, that in some cases he has not had the patience to await the necessary developments in pure physical chemistry, but has taken the law, or rather the laws, into his own hands, and laid the foundation stones of such developments himself. One need only

recall that the first precise measurements of osmotic pressure were made, not for chemical but for physiological purposes, by a botanist, Pfeffer: and that in more recent times Sir William Hardy, stimulated alike by the needs of biology and chemistry, has proved himself a pioneer not only in the field of colloidal chemistry, but also in the understanding of a subject which bulks largely m the mind of the physical chemist of to-day, namely, that of molecular orientation at interfaces. At the present time, the harvest reaped by this fruitful liaison appears to be not only maintained but also to be increasing, as is indeed shown by the work of A. V. Hill, Hober, Michaelis, and others. For that reason we cannot but extend a very cordial welcome to the latest edition of the most comprehensive treatise on the subject in existence—Hober's

'Physikalische Chemie der Zelle und der Gewebe" Hober's book consists of two main divisions. Of these, Part I deals with such portions of "the physical chemistry of homogeneous and heterogeneous systems" as are considered applicable to physiology, and hence includes chapters on osmotic pressure and diffusion, the ionic theory of solutions, measurement of hydrogen ion concentrations, surface phenomena, colloid chemistry and enzymes Unlike some writers, Hober shows himself equally at home both in the theoretical and practical -application of these subjects. The theoretical treatment is almost invariably sound, if not always quite up-to-date, and is so continuously and ingeniously interwoven with physiological applications that even the heart of the most biologically inclined reader must at times be softened. A physiologist should not fail to be more interested, for example, in the nature of osmotic membranes, when he learns so vividly from Chap. i that it was from the structure of the single plant cell that Pfeffer drew a leading hint as how to construct a really semi-permeable membrane. No less stimulating are the detailed discussions of the ionic theory of salt solubility (especially in connexion with uric acid and the solubility of its salts in the body fluids), and the comparison of suspensoid and hydrophile colloids, together with the application of this knowledge to the colloidal behaviour of living cells. Chap. vi., on enzymes, is perhaps the weakest in the book, but this can be readily excused by the German reader, who has access to the massive text-books of Euler and Oppenheimer.

It is to be hoped, however, that in future editions more attention will be given to the theory of ionic activity and its physiological successes, and that the fundamental work of Langmuir and Adam on

molecular orientation in thin films will receive more than the passing notice accorded in Chap iv. of the present edition A statement and appraisement of the divergent views on protein ionisation held by the respective schools of Pauli; Sørensen, and Loeb would also be welcome

Part 2 deals directly with the physical chemistry of cells and tissues and contains chapters on the body fluids, the osmotic properties and permeability of cells and tissues, narcotics, the physiological action of single electrolytes and ion combinations, electrical processes at physiological interfaces, absorption and secretion, and physical chemistry of matter and energy exchanges Here the author reaches his zenith, both as regards his powers of exposition and his usefulness to the reader. Each topic is summarised in a manner which is at once comprehensive, lucid, and well arranged, and though the discussions may be inferior in stimulating power to those of Bayliss in his "Principles of General Physiology," yet they contain much of great value in the way of criticism and suggestiveness.

It is difficult to select for special commendation from much that is good: but we venture to think that the treatment of cell permeability, Hofmeister ion series, antagonistic and co-operative action of different cations, and the recent work on kidney function will be found to be of the greatest value to the student, both on account of the intrinsic merits of these summaries and of their maccessibility elsewhere. In each case the reader is left with the impression that he has now got a really first-hand grip of the topic in question—possibly a dangerous delusion, but one of great help to him if he has to lecture on the subject

The last chapter, on the physical chemistry of matter and energy exchange, is in some ways the most fascinating, but is certainly the least complete. In further editions it is to be hoped that the sections on the temperature coefficients of vital processes and the action of light in biology may be expanded so as to include the recent interesting work on these subjects. But the most urgent need, in the opinion of the reviewer, is that some industrious and competent linguist should prepare an English translation of "Hober" and so render him more easy of approach by that growing group of scientific workers who are attracted to the borderland of physical chemistry and biology.

In conclusion it should be noted that Hober\* takes up no philosophical position in regard to the ultimate nature of life: he does not lay down that all living processes are reducible to the same

conceptual shorthand as physics and chemistry, nor does he deny it. He is content to indicate the great achievements already to the credit of this powerful shorthand, and to leave his readers in a mood of optimistic agnosticism as to the future. If ever there comes a limit to the extent to which physico-chemical interpretations of life can be pushed, that limit will surely be very much nearer to the ultimate goal of biology than anything that has yet been reached. Such is the impression derived from reading Hober's book, such, indeed, is the policy which directs and stimulates the majority of modern physiological research.

F. J. W R

## Rheumatism and Gout.

Aspects of Rheumatism and Gout . their Pathogeny, Prevention and Control By Llewellyn Jones Llewellyn Pp xiii+295. (London · William Heinemann (Medical Books), Ltd , 1927) 10s net.

In "Aspects of Rheumatism and Gout," Dr. Llewellyn, who has written much on these spa diseases, has collected the material of a number of his addresses and essays, many of them previously published, dealing with their pathogeny, prevention, and control, into an eminently readable and suggestive whole. In the foreword the plan of the work is outlined, and this is followed by a disquisition on diathesis, a subject which Sir Archibald Garrod has, since this volume appeared, treated in the Huxley lecture at Charing Cross Hospital; the rise, echipse, and revival of the diathetic conception are sketched, and diathesis is regarded as a synonym for chemical individuality.

The diathesis of acute rheumatism or rheumatic fever is characterised by an inborn tendency to a want of the normal endocrine-autonomic balance which is manifested by instability of the functions of the skin and is essentially an inherent deficiency in the power of organic regulation. Similarly, in rheumatoid or atrophic arthritis, in osteo-arthritis and gout, the author finds evidence of this endocrineautonomic imbalance, and further concludes that infections, if and when responsible for arthritis, act not directly but indirectly—the intermediary mechanism being instability or defect of the neuroendocrine system. As bearing on this view, the geographical correspondence in the incidence of goitre and of acute rheumatism and cardiac disease, which is so prominent in Bristol, is brought out. Later on, the resemblance of acute rheumatism to serum sickness, or the symptoms following injec-

tion of horse serum, is pointed out, and the view that infection causes the instability of the neuro-endocrine system, which is the exciting cause of the joint symptoms, is again suggested. In considering the prevention of acute rheumatism and heart disease, the importance of supervision in the pre-rheumatic phase is emphasised.

The relation of oral sepsis and arthritis, which has been so much in the limelight, is dealt with in considerable detail, and gout, on which the author wrote a book some seven years ago (1920), is described as a hereditary condition of hypersensitiveness to protems and analogous to asthma, the remarkable food idiosyncrasies of the gouty being brought forward to enforce the argument. It would thus appear that the gout-producing factor in alcoholic liquors is not the alcohol, but some protein such as hordem in beer and yeast cells in wine. A chapter is devoted to the common ailment lumbago, or pain in the back, and the difficulties in diagnosis are dealt with in chapters on the pitfalls in connexion with sciatica and arthritis. In conclusion, it should be said that the author's method of presenting his subject matter and style of writing add an attraction to the interest of these common diseases.

## Our Bookshelf.

Colloids: a Textbook. By Prof. H. R. Kruyt. Translated from the Manuscript by Prof. H. S. van Klooster. Pp. xi+262. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1927.) 17s 6d. net.

The author says in his preface that his purpose has been to write a text-book or, in other words, "to offer a main line of orientation to students who wish to become acquainted with the general trend of Colloid Chemistry or who desire to undertake research in this particular branch of Chemistry." The work may certainly be said to accomplish this purpose and to have solved the fundamental problem of text-book writing—that of selection from an enormous mass of material—with complete success.

A general introduction begins with a brief description of colloidal systems, gives in less than forty pages a clear and concise account of boundary phenomena, and concludes with a description of the electrical conditions at interfaces. The second part, the largest of the book, is devoted to suspensoid sols; a number of important generalisations from the vast mass of data on charge, flocculation, etc., are developed very clearly. The third part, dealing with emulsoid sols, departs more markedly than the rest of the work from traditional lines. The author takes as a type of this class the agar sol, which is certainly to be preferred to gelatin, and shows that its stability is a function of two factors, hydration

and electric charge, if either of these separately is reduced, the sol alters its character but remains The author is inclined to deal somewhat lightly with the anomalous viscosity of emulsoids, which have occupied both Freundlich's and Ostwald's laboratories considerably during recent years, but perhaps this is one of the simplifications made in the interests of the beginner, it is, however, certainly incorrect to say that a linear relationship between viscosity and concentration holds in agar, gum arabic, or starch sols, except at the very low concentrations and comparatively high temperatures at which the author and his students have chiefly examined them. In sols like those of indiarubber or cellulose nitrate it does not hold even at concentrations between 0 1 and 0 5 per cent. The remainder of Part 3 is devoted to protein sols, osmotic phenomena, and gels; though brief, these chapters are extremely lucid and instructive, and the reviewer has been struck particularly by the presentation and critical examination of Loeb's views A short fourth part deals briefly with special cases of interest, such as soaps and emulsions.

The translation is idiomatic and nowhere leaves the reader in doubt about the author's meaning. The book is excellently printed and illustrated.

E H

Eruptive Rocks: their Genesis, Composition, Classification, and their Relation to Ore-Deposits; with a Chapter on Meteorites. By Prof. S. J. Shand. Pp. xx+360. (London · Thomas Murby and Co.; New York: D. Van Nostrand Co., 1927) 20s. net.

Prof. Shand's interesting and original book is, as he says in the preface, the outcome of three msistent wishes: first, to clean up the "jungle of rock names". second, to make the results and conclusions of petrology intelligible to "matter-of-fact people like physicists and chemists" (we did not know before that petrologists were less matter-offact than physicists and chemists); and third, to "bring theory and practice together to save petrology from the reproach of being an academic study of little use in life" Prof. Shand has produced an admirably stimulating work, but we are not sure he has achieved the above aims. The classification of igneous rocks he has devised is based upon a sound plan, just as Esperanto is, but it may fail for the same reason that artificial languages fail, because it is too clean-cut and logical, and has not grown up with the science. He does not clean up the jungle of rock names; on the contrary, he adds to the undergrowth a number of new terms with the aid of the overworked prefixes and suffixes, per-, sub-, meta-, -oid, and the

The most successful part of the book, indeed, is not the classification, but the exposition of physico-chemical principles as applied to the crystallisation of natural magmas. This occupies the first five chapters, entitled "Eruptive or Igneous Rocks," "The Fixed Constituents of Igneous Rocks," "The Fugitive Constituents of Magmas," "The Magma and its Walls," and "The Freezing of

the Magma "Chaps. v1 to xiv. discuss classification m general, Prof Shand's own system and nomenclature, and descriptions of igneous rocks in relation to this system. The book concludes with chapters on meteorites and eruptive ore deposits

In describing the rocks assigned to various divisions of his classification, Prof. Shand has made a valuable survey of recent igneous petrography. The description of each main group is appropriately prefaced with a section on its geology, a feature often neglected in petrographical treatises. This book forms a very notable addition to petrological literature.

Second Experimental Report to the Atmospheric Corrosion Research Committee (British Non-Ferrous Metals Research Association). a Discussion held by the Faraday Society, 30th March 1027 By Dr. W. H J Vernon. Pp ii+113-204 (London: The Faraday Society, 1927.) 8s 6d. net.

It is quite impossible in a short survey to give any real indication of the amount of valuable information contained in this report. Systematic investigations on the indoor atmospheric corrosion of copper, brass, aluminium, lead, and zinc are recorded, whilst in the case of copper, brass, and zinc, outdoor exposure has also been examined.

Weight increment—time curves are given, and the value of the protective coating formed in some cases is revealed. The effect of oxide films on brass upon its subsequent corrosion in a polluted atmosphere is indicated. Exposure of zinc over a period of three years shows that, in an indoor unsaturated atmosphere, a straight line relationship holds except for the first twenty-four hours.

An outstanding feature of the report is the portion giving detailed analyses of the outdoor corrosion products, the proportions of sulphate, sulphide, carbonate, and oxides being determined. The corrosion product is shown to be less easily eroded in some cases than others. The deposit on copper is the most tenacious and that on zinc the least. In the latter case some 90 per cent. of the deposit is removed by weathering during outdoor exposure.

The influence of alloying impurities in the metals is not very appreciable during indoor exposure, but in certain cases it is very pronounced during outdoor exposure; thus arsenical copper and, to a lesser extent, copper containing nickel, is more resistant to attack than H.C. copper.

Some laboratory experiments upon the atmospheric corrosion of iron are included in the report. Solid suspended impurities in the atmosphere are shown to be responsible for the corrosion of iron in an atmosphere of low relative humidity. Screening the metal by preventing the access of such solid particles inhibits the corrosion. The influence of rust upon the subsequent corrosion of iron in an unsaturated atmosphere is also demonstrated.

In conclusion, the report embodies the results of a research covering a wide range and carried out with a patience and accuracy which can only be described as classical.

W. S. Patterson.

The Mollier Steam Tables and Diagrams extended to the Critical Pressure By Prof Dr Richard Mollier English edition adapted and amplified from the third German edition by Dr H. Moss Pp. xvi+53 (London Sir Isaac Pitman and Sons, Ltd, 1927) 7s 6d. net

RESEARCH is being conducted in order to obtain accurate knowledge of the physical properties of steam in the regions of high pressure and high superheat, but meantime the rapid development of the use of steam at high pressures and temperatures has accentuated the need for this information. To meet this temporary want, Dr. Molher has extended his tables of 1906, modifying the characteristic equation adopted in the calculations, in order to obtain results which agree consistently with all available data.

The form of equation, that recommended by Prof. Callender, has been retained, but an additional term has been found a necessary refinement at pressures above 30 atmospheres The method of testing this modified equation for reliability is briefly described. It is considered satisfactory for all conditions except for steam in the neighbourhood of saturation over a small range above 150 atmospheres, and the values in this range are obtained by reasonable extrapolation. The upper limits of the tables are the critical pressure and 500° C They are in a convenient form with notes on their practical application A table of coefficients intended to facilitate calculation and two large scale H  $\Phi$  charts are also included. Up to about 30 atmospheres, the values agree closely with previously published results, but in the higher pressure regions the differences are considerable and clearly justify the investigation. Although the book is only intended to have an ephemeral utility, it is a valuable contribution and should be highly appreciated by those interested in high L. M. D. temperature steam.

Les plateaux du Jura central : étude morphogénique.
Par Dr. Georges Chabot. (Publications de la Faculté des Lettres de l'Université de Strasbourg, Fascicule 41) Pp. 350 + 4 planches. (Paris : Société d'Édition Les Belles Lettres; London: Oxford University Press, 1927.) 12s. 6d. net.

The plateaux of the Central Jura are believed to be dislocated fragments of a Tertiary peneplain which have been caught up between the folded ranges. The author correlates this peneplain with that of the Swabian and Franconian Jura, and concludes that the plateaux are "relics of the tabular Jura within the folded Jura." His demonstration would have been more easily followed if it had been accompanied by more adequate maps and sections.

Some interesting chapters deal with the karst phenomena of the plateaux which are compared with the classic region of Illyria. The differences due to local climatic conditions, composition of the rocks, and geological history are clearly and convincingly discussed. The rainfall of the Jura is such as to encourage vegetable growth and continuous chemical action, with the consequent

greater accumulation of residual soil. The folded limestones are thin and alternate with impermeable beds: hence there is considerable run-off as well as constant infiltration. Changing climatic conditions in northern Europe have in the past sometimes promoted, sometimes retarded the characteristic processes of erosion. All these things impart to the karst of the Jura a somewhat hybrid character which is reflected in the peculiarities of the dry valleys, lapiés, dolines, and closed basins of the plateaux. This section of the book is worthy of the closest study.

Magnolias. By J. G. Millais Pp. viii + 251 + 34 plates (London Longmans, Green and Co., Ltd., 1927) 32s. net.

This book, which is well printed and handsomely illustrated, is a handbook to the cultivation of magnolias. The author is an enthusiast, with a great love and knowledge of gardening, and he pleads "for a big move in the planting of Magnolias throughout our islands so as to make England in April as lovely as Japan in cherry time." About forty species of Magnolia are known in the wild state, some deciduous, others evergreen, and all remarkable for their large and beautiful flowers Not all are hardy, but in Sussex at least twenty species grow in the open air. One of these flowers in March, another in October, and other species in the months between.

The duration of the flowering season is remarkable, and Mr. Millais urges that "Magnolias should be planted freely, since no other genus but Rhododendron will give so long a succession of beautiful flowers, without cultivation, expense, or effort on our part."

The greater part of the text is devoted to an elaborate account of all the species and hybrids, giving in each case a clear botanical description, with notes on cultivation and on remarkable specimens in well-known gardens. A key to the genus by Mr Dendy, of Kew, and a special chapter on the magnolias of Yunnan in China by the intrepid explorer, G. Forrest, add to the interest of the book. Another useful chapter gives an alphabetical list of the names and synonyms that have been applied to the species and hybrids.

How a Tree Grows. By Sir Wılliam Somerville.Pp. iv + 212. (London: Oxford University Press, 1927) 10s. net.

This is an elementary treatise on forest botany, based on lectures given to students of forestry at Oxford. It is written in an easy style, and may be perused with pleasure by working foresters, gardeners, landowners, and others interested in growing trees and in the production and sale of timber. The book is well illustrated with more than a hundred diagrams and figures. Many subjects besides that indicated by the title are briefly but clearly dealt with, such as buds, leaves, stipules, seeds, seedlings, fall of the leaf, mycorrhiza, ascent and descent of sap, etc. Most attention is paid, however, to the structure and properties of wood and to the identification of timbers. A good index is provided.

#### A Contribution to the Piltdown Problem.

SINCE the discovery of the fragments of the Piltdown skull in 1912, there has been considerable difference of opinion with regard to the manner in which the skull should be reconstructed, and as a necessary consequence of this, with regard to the extent of its cranial capacity.

cranial capacity.

Estimates of this have ranged from Smith Woodward's original figure of 1070 c c. (see Nature, vol 92, p. 197; 1913) to his latest estimate of about 1300 c.c. a figure which is approved of by Elliot Smith (see Nature, vol. 109, p. 726, 1922). Keith, on the other hand, at one time estimated its capacity at just above 1500 c c, by measuring the amount of water displaced by the endocranial cast taken from one of

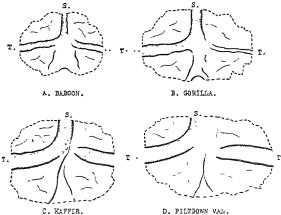

Fig. 1—The stippled areas in the above drawings represent the arrangement and proportions of the venous sinus grooves (transverse sulci) on the internal aspect of the occipital bones of the skulls of: A A baboon with a cranial capacity of 188 c c, B. A gorilla with a cranial capacity of 527 c c; C A Kaffir with a cranial capacity of 1880 c.c; and D. Piltdown man with a cranial capacity of 1415 c.c, estimated from the width of the transverse sulci (T).

his reconstructions (NATURE, vol. 92, p. 197; 1913), but his most recent view, derived from an application of Lee's formula to one of his reconstructions, appears to be that the cranial capacity is about 1400 c.c. ("The Antiquity of Man," by Sir Arthur Keth, vol. 2, 1925). All these estimations were determined from different types of reconstruction, the accuracy of which is disputed, and so far there has not seemed to be any other way of arriving at an estimate of the cranial capacity, and in this way helping to decide whether the higher or the lower estimates are more likely to be correct.

On examining the endocranial aspect of Mr. Barlow's casts of the Piltdown bones, one is struck by the large size and clearness of outline of the grooves for the middle meningeal vessels on the parietal fragments, and of the transverse sulci, that is to say, the grooves for the transverse venous blood sinuses on the occipital fragment. Now the large size of these grooves and of their corresponding blood-vessels does not appear to have been sufficiently emphasised as an indication of the size of the brain-case, for they seem in themselves to suggest a moderately large brain cavity.

That the size of the transverse sulci is correlated with the capacity of the cianium in a definite manner is clear from Fig. 1, masmuch as these sulci are much narrower in a baboon than in a gorilla, and narrower in a gorilla than in man. This is what one would expect, seeing that these sulci lodge the veins, which convey practically all the venous blood returning from the brain. Larger channels are therefore needed for the larger amount of blood returning from larger brains.

A number of observations have therefore been taken on a small group of human skulls to test the degree of correlation between the width of the sulci and the cranial capacity, with the view of arriving at a means of determining the cranial capacity from the width of the sulci.

Cramal capacity	Average width of right and left sulci	Cranial capacity
1300 c.c.	$16~80~\mathrm{mm}$	1370 с с.
1436	17 26	1360
1320	$17 \ 33$	1270
1130	17 80	1406
1615	18 10	1445
1410	18 20	1380
1250	18 30	1450
1280	18 35	1385
1290	18 45	1315
1270	19 40	1420
1450	19.48	1285
1170	19.50	1550
1380	$19\ 52$	1315
1350	19.75	1475
1320	$20 \ 70$	1580
1266	21.00	1665
	capacity 1300 c.c. 1436 1320 1130 1615 1410 1250 1280 1290 1270 1450 1170 1380 1350 1320	capacity right and leit suici 1300 c.c. 16 80 mm 1436 17 26 1320 17 33 1130 17 80 1615 18 10 1410 18 20 1250 18 30 1280 18 35 1290 18 45 1270 19 40 1450 19 48 1170 19 50 1380 19 52 1350 19 75 1320 20 70

The coefficient of correlation between these two variables, in the thirty-two skulls measured, is 0 475, which is definitely significant. The regression formula for the calculation of the cranial capacity in terms of the width has been found to be as follows:

Cramal capacity =  $27.98 \times \text{width} + 894.2$ 

In connexion with this equation there is a probable error of  $\pm 69~0$ 

The average width of the two transverse sulci of the Piltdown occipital bone added together is 18 6 mm. The cramal capacity is therefore estimated from the above formula to be 1415 c.c., or to he somewhere between a lower limit of 1346 c.c. and an upper limit of 1484. This makes the Piltdown skull mesocephalic, and supports those who have arrived at this conclusion by other methods.

Mr. S. Cohen and Mr. P. R. v d. R. Copeman kindly assisted me in taking the measurements and in making the calculations.

M. R. DRENNAN.

Anatomy Department, University of Cape Town.

# γ-ray Emission and the Law of Radioactive Transformation.

Some time ago I described a method (*Phil. Mag.*, vi. 47, 23; 1924) of determining the period of transformation of RaC', which consisted essentially in comparing the transformation constant  $\lambda$  with the velocity v of the recoil-atoms from RaC. The apparatus is shown in Fig. 1a: the active source, which consists of RaC deposited on nickel, is placed on the cone in the lower end of the apparatus. A beam of recoil atoms is limited by the screens S; midway between the screens a number of slits is provided through which the  $\alpha$ -particles from the recoil atoms

No. 3033, Vol. 1201

are observed. If the transformation of RaC' takes place according to the law

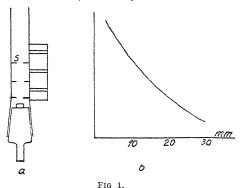

$$N_t = N_0 e^{-\lambda t}$$
, . . .

where t=0 represents the moment at which the  $\beta$ particle is sent out, it is easily shown that the number of a-particles as a function of the distance x from the active source to the slit will be represented by

$$n = n_0 e^{-\frac{\lambda}{v}x}. (2)$$

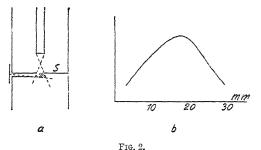

The experiments showed that the number of aparticles decreased approximately exponentially with increasing distance from the source (Fig. 1b), the value obtained for  $\lambda : v$  being about 1.

Later on, Barton (Phil. Mag., vii. 2, 1273; 1926)

repeated the experiment with an apparatus somewhat different in construction and obtained a similar value for  $\lambda : v$ .

In the course of a series of experiments, the object of which was to obtain a determination of v by measuring the stopping power of gases for the recoil atoms, the apparatus shown in Fig. 2a was used among others. The active source is again RaC, deposited on the flat end of a nickel rod 4 mm. in diameter; by means of a

screen S with a circular hole 4 mm. in diameter a beam of recoil atoms is defined — The  $\alpha$ -particles emitted by the recoil atoms are observed through a flat tube  $2\times 10$  mm. in cross-section, which is placed immediately below the screen The number of a-particles observed will be proportional to the number of recoil atoms transformed in the hatched space. By means of a screw arrangement, not shown in the figure, the distance between source and screen could be varied.

The result of an experiment is shown on Fig. 2b, where the number of  $\alpha$ -particles is plotted as a function of the distance between source and screen; a correction has been applied for change in the solid angle covered by the beam of recoil atoms when the source is moved. It is seen that the number of  $\alpha$ -particles with increasing distance rises from zero to a maximum value, from where it again decreases.

By a comparison of the curves in Fig. 1b and Fig. 2b

a striking disagreement is found; obviously in one or both of the corresponding apparatus a source of error must be present which has hitherto been overlooked.

The origin of this difference in behaviour of the phenomenon may be briefly summarised as follows From the work of Knudsen and Langmuir it is known that when atoms of mercury collide with a glass surface they will in general be reflected by an elastic collision, but no condensation occurs when the temperature is above a certain critical value. The collisions between the recoil atoms and the metal walls in the apparatus in Fig. 1a may be expected to behave in a similar manner. When a solid obstacle is placed in the path of the recoil atoms, an accumulation of recoil atoms will This will especially be the case in the space between the first and the second screen in the apparatus Fig. 1a, which will act as a trap for the recoil atoms. When a recoil atom has suffered a collision with one of the walls, the chance for getting out of the space in question without being transformed will be relatively small. It is clear that the number of α-particles emerging from the first slit may be increased several times in this way. For the slits at longer distances from the source a similar effect will be present, but not to the same degree.

The conclusion here arrived at could be verified by placing screens in the path of the recoil atoms in the apparatus Fig 2a; when the distance source-screen was 5 to  $10~\mathrm{mm}$  , the number of recoil atoms could be increased from 2 to 5 times in this way; at longer distances the increase was relatively smaller. From these considerations we may conclude that the decay curve for RaC' has the shape shown in Fig. 2b, and that the apparently exponential decay shown in Fig. 1b has its origin in the source of error outlined above. In the apparatus used by Barton this source of error is not present. The reason that Barton observed a steady decrease in the number of aparticles with increasing distance, seems to be that the regions, which in his apparatus corresponded to the hatched part in Fig. 2a, were broader and at

longer distances from the source.

At first sight the curve in Fig. 2b might be taken to indicate a deviation from the general law of radioactive transformation, the transformation constant  $\lambda$  depending upon the time. A closer consideration shows, however, that a more reasonable explanation, in which the transformation law is conserved, can be obtained by taking into consideration the time required for the emission of the γ-rays It is known that a nuclear electron is sent out from RaC and an a-particle from RaC'. According to Ellis and Meitner, the emission of the  $\gamma$ -rays must be placed between these two, such that the following picture is obtained:

At the time t=0 the  $\beta$ -particle is sent out and the movement of the recoil atom started. The  $\alpha$ -activity of the recoil atom will now vary in the same way with time as if the  $\gamma$ - and  $\alpha$ -rays were sent out from two consecutive radioactive substances When both the γ- and the α-transformation are assumed to take place according to an exponential law (1), and the constants  $\lambda_{\gamma}$  and  $\lambda_{\alpha}$  are adjusted in a suitable way, the curve in Fig. 2b for the  $\alpha$ -activity will result. From the shape of the curve it appears that  $\lambda_{\gamma}$  and  $\lambda_{\alpha}$  must be of the same order of magnitude. By putting  $\lambda_{\gamma}$  equal to  $\lambda_{\alpha}$  and assuming for v, the velocity of the recoil atoms, a value of  $2 \times 10^5$  cm. per sec.,  $\lambda_{\gamma}$  is found equal to 10<sup>5</sup> sec.-1.

This can only be regarded as a rough approximation, since the recoil  $h\nu/c$  due to the emission of the  $\gamma$ -rays has been disregarded. As a result of this, neither the solid angle covered by the beam of recoil atoms nor the time can be simply determined from the distance source-screen.

Experiments are in progress to test the following

two points.

(1) In the case of ThC',  $\lambda_a$  from the Geiger-Nuttall formula may be expected to be very large — Provided  $\lambda_{\gamma}$  is of the same order of magnitude as the velocity of the recoil atoms from ThC, we should expect to find an exponential decay of the a-activity of ThC' with time.

(2) When a preparation of RaC deposited on nickel

(2) When a preparation of RaC deposited on nickel is placed in a vacuum, part of the  $\gamma$ -radiation should originate from the space surrounding the source; by a suitable screening it should be possible to detect a variation with the pressure in the apparatus of the ionisation due to the  $\gamma$ -rays

I desire to express my thanks to Prof. Bohr for the interest he has taken in the work.

J. C. JACOBSEN

Institute for Theoretical Physics University, Copenhagen, Oct. 14.

#### The 'Green Flash.'

REFERRING to Sir Oliver Lodge's conviction that the green flash at sunset is mainly physiological (NATURE, Dec. 3, p. 807), I would point out that this does not explain the appearance at sunrise. green flash has been seen at sunrise by numerous observers; I have myself seen it repeatedly. As seen through field glasses the green flash at sunset has no appearance of being physiological; the two ends of the last visible segment of the sun take on the green hue first, and this spreads rapidly over the whole segment as it grows smaller, until the last visible part of the sun becomes a vivid blue green. This appearance as seen through field glasses has been described more than once. The green flash is only seen when the sun sets behind a distant horizon, whether this be sea, land, or cloud, as would be expected if the flash were due to refraction. If the cause were physiological the flash should be seen when the sun sets behind a horizon close at hand, but so far as I know this is not the case.

With regard to Sir Ohver Lodge's observation of the appearance of a momentary greenness when he switches off a bright light, I have tried a similar experiment (1) with the naked eye, when the first after-image seemed to me to be golden; (2) looking through a yellow, Wratton G, filter, when the first after-image was a deeper gold; and (3) through a deep red, Wratton A, filter, when the first after-image was a very deep red. Some seconds later, when its intensity began to fade, the after-image became a dirty green, and this lasted for a considerable time. Probably different observers react differently, for I notice that my two eyes react in a slightly different manner. It would be interesting to know whether the greenish appearance mentioned by Sir Oliver Lodge has any of the vividness and distinctness of any of the appearances of the green flash that he may have seen.

The green flash at sunrise and sunset lasts a very short time. I should estimate it as half a second at most as seen with the naked eye; it does not fade away gradually as would an after-image, but 'goes out' suddenly at sunset, and at sunrise it changes as suddenly to the yellow of the sun. The appearance at sunrise seems to me definitely to rule out the physiological explanation.

The literature of the green flash is very voluminous, and extends into fiction, but the whole subject was

dealt with by Dr A A Rambaut in the Meteorological Magazine, vol. 41, pp. 21 and 41. After reading these articles, and after having myself seen the green flash many times both at sunrise and at sunset, I can feel no sort of doubt that the explanation is physical and not physiological The explanation as a refraction phenomenon is so simple, and fits the facts so well, that it is curious that there should be such a reluctance to accept it.

C. J. P CAVE.

Stoner Hill, Petersfield, Hants, Dec. 3.

MUCH confusion has beset this subject, because two entirely different things are unfortunately covered by the phrase 'green flash' If separate names had from the first been given to the two things, each would have been treated apart from the other and a great amount of controversy avoided. A greenish light appears as a physiological effect on ceasing to look at the red disc of the setting sun, as Sir Oliver Lodge points out in NATURE of Dec. 3. But there is also a purely physical phenomenon of sunset which is seen at the instant when the last portion of the sun's disc disappears on a sharp horizon During the years when I was much at sea I used to watch every clear sunset, and rarely failed to observe this phenomenon though it was sometimes incomplete It appeared at its best on half-a-dozen occasions when the thinnest segment of the sun's disc was still above the horizon, but with its light so much reduced that it could be looked at easily through a field-glass. However red the sun may have been when fully visible, the tiny shaving of a flat are had become distinctly yellow, and as it was disappearing, the ends turned greenish and seemed to shrink towards the centre, at which the last light visible seemed to be intensified to a clear green point, which changed into blue and vanished in violet in a fraction of a second too short to estimate

During the visit of the British Association to South Africa in 1905, I had many arguments on the subject with sceptical fellow-members, some of whom denied the existence of a green ray, and others explained it as an optical illusion or an effect of fatigue of the retma. The sturdiest doubter was Dr. A. A. Rambaut, the Radcliffe Observer at Oxford, but at last he saw the light from the deck of the Durham Castle as the sun was setting behind Cape Guardafui. A few days later, he, along with Sir Henry Miers and others, caught the first rays of the rising sun and found the colours change in the reverse order from blue or green to yellow. Dr. Rambaut went into the matter fully in a paper, "The Green Flash on the Horizon," published in Symon's Meteorological Magazine for March and April 1906 (vol. 41, pp. 21-23, 41-45). His explanation was that the images of the sum formed by light of definition. of the sun formed by light of different wave-length are not exactly superimposed, and that as the last of the disc passes below the horizon the red image disappears before the yellow, the yellow before the green, and the green and blue images respectively go before the violet image fades. The duration of this change was worked out for various dates and different latitudes, and the conclusions arrived at in this paper have not been controverted so far as I know.

HUGH ROBERT MILL.

Dec. 3.

The physiological theory of the green flash, resuscitated by Sir Oliver Lodge, is not now held by any competent observer who has made a careful study of the phenomenon. The late Mr. Whitmell was, I

believe, the first to arrive at the correct and simple explanation, and he was the first to describe the red flash. His observations are. I believe, recorded in back numbers of NATURE, and in other journals

I have made very numerous observations of the green flash, at sea and on land, and have confirmed

Mr Whitmell's conclusions

If the sun is observed in an achromatic telescope when near the horizon, a green fringe is seen round the upper limb, and a red fringe round the lower limb, due of course to atmospheric dispersion. This green upper segment remains visible for about a second or perhaps two after the sun has set, and it sometimes turns a beautiful violet at the last instant if the atmosphere is clear enough to transmit violet light. The green may be seen with a telescope or binoculars at any sunset or sunrise, in clear air and with a low horizon. It is conspicuous to unaided vision only under certain conditions at sea, when mirage effects enhance its brilliancy (Nature, vol 111, p. 13).

The red fringe may also be seen when the lower limb emerges from the sharp boundary of a dense cloud near the horizon, but the necessary conditions

for seeing this 'red flash' are rare.

J. Evershed.

Highbroom, Ewhurst, Guildford, Dec 3.

This summer, six of us were watching the sun set behind the hills of Jura in a sky absolutely free from cloud and haze. We stood on a moderately high hill, and the sea, four miles broad, lay between us and Jura. Four had not even heard of 'the green ray' I, who had seen the ray on other occasions, suggested that five of us should turn our backs to the sun and close our eyes until the sixth should signal that the upper edge of the sun was disappearing. On his signal we turned, and each saw for an appreciable time a thread of bright green light lining the silhouette of the island at the point where the sun was last seen. In the case of the five, at any rate, this could not have been a subjective after-image.

WILLIAM SEMPLE.

Mile Ash, Dumfries.

## Chinese Alchemy.

COMMUNICATIONS upon the subject of Chinese alchemy have appeared several times in NATURE during the past year by Prof. J. R. Partington and have greatly interested me. The Pent'sao and similar books upon Chinese mineral drugs make repeated reference to the transmutation of metals into gold. However, few of these books have very old editions extant, so I have been looking up the subject of alchemy from other sources.

With the help of Mr Chen Yung, I have made the following abstracts from books referring to this

(1) 116 B.C., Ssu Ma Ch'ien wrote "The Shih Chi." He discusses the history of Ch'in Shih Huang Ti (221 B.C.) and states: "Hsu Shih led several thousand boys and girls to search for the immortals in the sea, where there were three mountains, P'eng lai, Fang shan, and Yin chou

"Ch'ın Shih Huang Tı was unable to find the miracle medicine 'ch'i yao' because things came to harm him; but after he had been protected from the

devils, he was able to find it.

"Lu Sheng wished Ch'in Shih Huang Ti not to let

others know where he lived, then he can obtain this

medicine of immortality, 'Pu ssu chih yao.'
"Ch'in Shih Huang Ti directed a large number of scholars and magicians to make the country peaceful

by producing the magic medicine

Li Shao-chun said to Han Wu Ti, cinnabar can be smelted to form pure gold; this made into eating utensils, when used will produce longevity: with longevity one is able to visit the immortals of the P'eng lai mountain, the worship of whom will bestow immortality.

"Then Han Wu Tı sent the Fang Shih into the sea to find the immortals of the P'eng lai mountain, and others he sent to smelt cinnabar with other medicines

to change them into gold.

'Although much money was spent they did not succeed in finding the immortals and immortality.

(2) 92 B.C. In the Shen-hsien-chuan we read that the "King of Huai nan," named "Liu an," kept several thousand people who wrote many books, of which eight chapters were upon the immortals and alchemy.

These writings are repeatedly referred to in other works. They are now lost, but their existence and

substance matter were definitely established.

(3) A D. 142. Wei-Po-yang wrote the "T'san T'ung Ch';" which he stated was the first book on internal alchemy (nei chin tan). It is included in the "Ssu-ku-ch'uan-shu" (the Imperial Encyclopædia), which establishes its reliability in the eyes of the Chinese. In the chapter upon "the creation of true earth" he refers to "the many fruitless attempts of men to make the philosopher's stone, by heating together Tangut ore, talcum, alum, magnetic iron ore, and sulphur These are useless, because they are foreign to the body. Used a thousand times they will fail ten thousand."

He believes in immortality from the true harmony produced by water and earth in the body, but he expressly opposed the alchemy of his day which tried

to produce immortality by chemical means.

Ko Hung, in writing "Pao P'u Tzu," states that
"Wei Po-yang was the 'Father of Alchemy,' and had three disciples who went into the mountains to make medicines. When made, they first tried them on dogs to see if they were fatal or immortal in their effects. Dogs died when fed on them; one of the disciples ate one and he also died. Wei Po-yang also ate one and died, etc. When they were being put into their coffins they resurrected." This account occurs in "Li-tai-shen-hsien-ch'uan," which is not so trustworthy as the "Tsan T'ung Ch'i."

I should like to emphasise in this material two

points ·

(1) Prof. Partington agrees that the accuracy of Ssu Ma Ch'ien's work seems to be unquestionable. In this we read, Ch'in Shih Huang Ti directed a large number of magicians to make the philosopher's stone. Now a large number could not have been in existence if alchemy had not been already well established by that time, 221 B.C., as concluded by the writers of the Bengal Monograph.

(2) The writings of Wei Po-yang are apparently quite authentic. The book I have quoted makes constant reference to the pill of immortality and the many schools which supported the use of mineral drugs to produce immortality, whereas the writer claimed the production of internal harmony as all important to immortality. His treatise implies a well-established school of alchemy in his day which also antedates

" Pao P'u Tzu.'

If the above evidences be accepted, it gives further strong support to the independent origin of Chinese alchemy, that it antedated the Egyptian school, and

that it certainly alose earlier than the conquest of Egypt by the Arabs, AD 640 It does not seem probable, when all is considered, that Beithelot was right in considering that Chinese alchemy was B. E. READ. derived from the Arabs

Peking Union Medical College, Peking, Oct. 22.

THROUGH the kindness of the Editor of NATURE, I have had an opportunity of seeing Prof Read's interesting letter. The citations which he gives from Sse Ma Tsien's chronicles (a careful translation of a portion of which by Chavannes has been published), and the reference to books on alchemy in 92 B.C., indicate an early date for the practical study of this subject in China. No one who has read the information available in translations such as these can, it would seem, agree with the hypothesis of Arabic transmission put forward by Berthelot on such slender evidence, and dogmatically repeated by later writers, some of whom have added to the confusion by citing the conclusions of authorities in a form which is the exact opposite of that held by the authors to whom reference is made. Anyone who is interested in Chinese alchemy is recommended to refer to careful translations of Chinese books, where these exist, and to ignore the very uncritical and garbled accounts of the subject given in recent com-pilations on the history of alchemy. I have already alluded in NATURE to the entirely independent support given to my suggestions by the valuable work of Stapleton and Azo. It appears that the ground is gradually being cleared, and if Chinese experts can be induced to render some assistance, a new chapter on the transmission of alchemy to the West may soon be written.

J. R. Partington.

## Dynamics of Whirlwinds.

IN NATURE of Oct. 8, J S. Dines gives an example of small whirlwinds in which the reduction of pressure at the foot of the central core was much greater than it could possibly have been at the top of the column, and further compares this with the case of an actual

tornado where the same thing evidently takes place. In the Quarterly Journal of the Royal Meteorological Society for 1896, page 71. W. H. Dines described an artificial tornado cloud which he produced by very simple means, and stated that this phenomenon was observable to a marked degree in his model. With a rotating column about two feet in height he found it possible to get a reduction of pressure equivalent to about 1 inch of water at the foot, while at the top the fan which was employed to cause the updraught was incapable of producing a suction of more than about d of an inch.

There is no difficulty in explaining the low pressure at the foot, but what we have to explain is why air does not flow down the core from the top and ultimately equalise the excess reduction of pressure. I suggest that the reason is to be found in turbulent motion of the air comprising the column. There are good reasons for supposing that there is considerable turbulence, and in such case there is no reason why a pressure gradient along the core should not exist.

Consider some definite portion of the vortical column, let r be the distance of an air particle from the central axis, p the pressure,  $\rho$  the density, and v the velocity component resolved perpendicular to the axis,

Then 
$$\frac{dp}{dr} = \frac{\rho \cdot v^2}{r}$$
. . . . (1)

The question now arises as to what relation exists

No. 3033, Vol. 1201

If there be no turbulence the between v and rprimary determining factor will be the viscosity of the air, and this will always tend to make any section of the column rotate like a solid disc, that is, v/r will be

If, then, we neglect changes in  $\rho$  we have from (1) the equation

$$\frac{dp}{dr} = \rho \cdot k^2 \quad r, \text{ where } k \text{ is a constant,}$$

$$p = \frac{\rho \cdot k^2}{2} \cdot r^2 + \text{constant.} \qquad (2)$$

On the other hand, if the motion be turbulent there will be a continuous interchange of angular momentum between the different concentric shells, and the tendency will be towards the product  $(v \mid r)$  being constant.

In such case we should have

$$\frac{dp}{dr} = \rho \cdot k_1^2 \frac{1}{r^3},$$

$$-\frac{\rho \cdot k_1^2}{r^3} \cdot \frac{1}{r} + \text{constant}. \tag{3}$$

 $p = -\frac{\rho \cdot k_1^{\ 2}}{2} \cdot \frac{1}{r^2} + \text{constant.} \qquad . \label{eq:posterior}$ whence

Actually, it seems certain that some relation lying between these two extremes must exist, but since the viscosity of air is small it is probable that the conditions are more nearly represented by (3) than (2). It will be noticed that equation (3) implies the existence of a small intense core of low pressure, but that (2) does not, while we know from observation that such a core does exist in the centre of a whirlwind.

The high values of v/r near the centre and consequent low pressure could of course be produced without the aid of turbulence if some external source of energy continually extracted air from the centre, but since the pressure gradient along the core is of the wrong sign for this to happen, we are left with the inference that turbulent motion must be the true cause of it.

The outer shells of a whirlwind are known to have a helical motion upwards and around the core, and if it be granted that the whole motion is turbulent they will continually exchange momentum in the axial direction between themselves and the central core. This explains both the axial pressure gradient and the reason why air does not flow downwards towards the region of low pressure.

Another point was raised, but not answered, in the paper of W. H. Dines, referred to above; namely, the curious fact that the central core in his model tornado cloud was comparatively clear, while the surrounding shells were dense with cloud particles Now it is immediately calculable that if a suction of 1 mch of water can be produced in the centre of a whirl not more than a few inches in diameter (which was approximately the case in the model in question), the radial acceleration of the air comprising it must be of the order of 500 times that of gravity. Such an acceleration will throw all the larger water particles out of the air in the central region into the outer shells, where the acceleration is smaller; it would be interesting to know if the same thing happens in the ordinary small waterspout or dust whirl, and in the larger American tornado. L. H. G. DINES.

#### The Struggle for Existence.

DARWIN attributed organic evolution chiefly to the combined action of variation and the struggle for existence, primarily the competitive struggle. This involves certain difficulties. First, the factors named tend to mutual exclusion—the more variation the less struggle. Secondly, were there no variation,

competition would be intense but barren; were variation so discontinuous as to exclude competition, many certainly of the variants would perish, but others would prosper, and since there would be greater variety than under competitive conditions, there would also be more abundant life and perhaps greater evolutionary progress. Thus, where competition is greatest the results for evolution are mil, where the results are greatest competition is absent.

The question then ensues, how does competition or, as I would call it, incompatible similarity, operate? In relation to variation, or rather to fit variation, incompatible similarity is perhaps best regarded as part of the environment. As such it is directly related only to the comparative fitness of certain variations fitly related to other environmental features; these variations it tends to specialise indefinitely, because adaptation to it only produces further incompatibility, necessitating further adaptation, and so on. But it is only on fit variations which, as discontinuous, considerably lessen, while not excluding, incompatibility that this incompatibility can operate. I assume discontinuity since the older view of natural selection as operating on minute innate differences is now found to involve serious difficulties, besides which I would suggest another, namely, that such differences would count for less than certain acquired differences—generally the surviving fittest would be those in the prime. Again, at least in progressive evolution, there is increasing environmental variety, partly due to the diffusion of life beyond the area in which it began into other and unlike areas, partly an actual increase in both organic and inorganic variety. There is also, I should suppose, at least until types have become much specialised, increasing germinal variation, attributable partly to greater environmental variety as affording richer means of subsistence. This general diminution of similarity involves a diminution of incompatibility, and therefore of its characteristic action upon variations. Decreasing fecundity as evolution advances also means decreasing similarity and incompatibility.

Regarding now the bearing of the above on the question how far relations of support, how far those of conflict are involved in natural selection. Fit organic variation obviously develops relations of support, at first one-sided, later becoming mutual as between organism and organic environmentwhile later again actual co-operation among organisms, chiefly similar organisms, emerges. Relations of support, however, involve acute conflict where one race supports another as prey. Competition in mtensifying certain qualities of fitness intensifies relations of support. Very largely, however, it affects such relations where they involve conflict, and this also it intensifies. Besides which it has itself an aspect of conflict, especially where there is direct That fit variation, so far as involving increased help, has been much the more important progressive factor is suggested upon comparison of the results of evolution on land with its results in the much more extensive and less divided sea, where, partly at least from the scantiness of plant-life, competition involving conflict in its severest form has altogether preponderated. This conclusion, I would note, might help to reconcile the scientific conception of Nature with its æsthetic appeal.

The noncompetitive struggle is perhaps not a factor in evolution at all. For the total organic production is here the real cause of evolution as including by the law of probability, apart from any orthogenetic or Lamarckian tendencies, the production of a certain proportion of fitly varying organisms.

The surviving fit—not fittest—here find Nature more helpful than hostile, and so strive perhaps rather than struggle, the unfit succumb without influencing the evolutionary process, in relation to which their struggle is therefore a useless by-product

P. J. Hughesdon.

#### Meteorological, Geological, and Biological Conditions on Venus.

The absence of oxygen in the atmosphere of Venus, as shown by St John's spectroscopic observations, and the consequent absence of life such as we know, are scarcely what one would expect at first sight on a planet so much like the earth in size and mass and having a mean temperature within the range of terrestrial abodes of life. An explanation, however, is suggested by further consideration of what might happen to the earth and its inhabitants if it could be transferred to the orbit of Venus, and also have its axial rotation speed reduced to one revolution in several weeks.

The changes of temperature produced by these two changes would of course be great, but would they alone eliminate life? The orbital change, doubling the supply of heat, would raise the mean temperature of the upper atmosphere by some 40° C., or perhaps less if we allow for an increase of albedo to that of Venus. This would leave even the tropics within the range of temperatures of such hot springs as contain life, and the polar regions would merely become comfortable.

The rotational change would increase the diurnal range of temperature seriously, but not so much as if the change of duration of the day's heat supply were the only factor to be considered. One mitigating factor is the increased moisture content, produced by the increase in average temperature. This would increase the thickness of the moist or cloudy region through which the solar heat must penetrate to reach the ground, or in which the radiation leaving the ground at night would be absorbed. The other mitigating factor is wind. On the earth as it is, the well-known deflexion of winds by its rotation limits greatly their ability to carry cold air to heated regions; on our hypothetical, transferred earth, this deflexion would be nearly eliminated. Thus the temperature differences would be so restricted by wind that it seems difficult to deny the existence of life on their account, especially in the polar regions.

The effects of this wind, however, would not all be so beneficial. For not only is the temperature range causing it great, even if not too great for life, but a wind blowing along the lines of the pressure gradient must acquire kinetic energy with far less loss by friction than occurs in our deflected winds. Hurricane strength at least, therefore, looks reasonable, and continual hurricanes would soon produce vast changes in our hypothetical, transferred earth. Vegetation on the land would be greatly impaired, leaving the surface exposed to wind erosion; in the tropics the increased violence and frequency of the thunderstorms (especially with increased temperature and moisture content) would add greatly to erosion by rain; along the coasts, likewise, wave erosion would be greatly accelerated. Altogether, would the continents endure? Or even if they could be maintained temporarily, by unusual orogenic activity, such as characterises the present geological epoch, could they endure under more normal conditions?

If they could not, the result would be a planet completely covered by its ocean, with water so rough as to give notable erosive action at depths at least comparable with that to which sunlight can penetrate Land plants would then be absent, and perhaps even shoal-water plants as well. and the question arises, Could the plankton algae produce enough oxygen by photosynthesis to show in St. John's spectroscope?

Furthermore, assuming they could, on this hypothetical transferred earth, would there be any plankton algæ on a planet that had never had any continents, and so had never had any quiet tidal pools, such as are often described as the probable origins of life on

the earth?

In short, is it not reasonable to suppose that Venus is a planet without land, without shoal water, and therefore without life? There are many questions here for the geologist and the biologist which a physicist cannot attempt to answer.

DAVID L. WEBSTER.

Stanford University, California, Oct. 24

#### The Tribal God.

I FEAR Prof. MacBride (NATURE, Dec 3. p. 807) has entirely failed to distinguish between speaking contemptuously of the Deity and of some people's conceptions of the Deity. He has also withdrawn from mine and Mr Squire's context the explanatory text. This is a common failing of the journalist, but

ought not to be of the scientist

My words in the lecture run as follows: "Nay, even to understand the Reformation itself you must appreciate that it was the replacement of a universal church by separate national churches, and in no forced sense a real return to tribal gods, invoked to support and render victorious their individual nations. Nay, if you kept your eyes open during the recent world war, I think you would have found many traces of religion as a tribal faith. This conception is strikingly expressed in the lines which Mr. J. C. Squire wrote in 1915 or 1916:

"God heard the embattled nations' charge and shout 'Gott strafe England' and 'God save the King,' God this, God that, and God the other thing. 'Good God!' said God, 'I've got my task cut out'"

To me, and I should imagine to many readers of Nature, the conception of a God of Battles, to whom appeal is made to aid one or another nation in killing millions of their fellow-men, is contemptible, the product solely of ignorance. It is as barbarous an idea as that of the Greeks of Homer's day that the gods could mingle in the fray of men, killing mortals and wounding each other. When Ares and Athene assist their rival heroes, surely Zeus has his task cut out! May I not say to Prof. MacBride as Diderot to the god-makers of his day: "Détruisez ces enceintes qui rétrécissent vos idées! Élargissez Dieu!"?

KARL PEARSON.

University College, Gower Street, W.C.1.

#### Flame and Combustion.

Doubtless readers of Nature will have noted that, although twice challenged by us to say what evidence there is for his notion that not 'hydrone' (steam) but something much more complex and 'hydronolic' (water) is formed by combustion in flames, Prof. Armstrong has vouchsafed no answer. If his fertile imagination cannot frame one we may be sure none is forthcoming, so that judgment will now go by

detault, however much in his closing speech he may gibe at his opponents

So far as we are concerned, whilst making no pretence of having solved completely the whole problem of the precise rôle played by steam in the combustion of carbonic oxide—preferring to keep our minds open to the new evidence which is now rapidly coming in from various quarters—we wish in a closing word on this part of the case to say that in our opinion a point has been reached when it can be said quite definitely that the cumulative weight of experimental evidence is so conclusive against Prof. Armstrong's extreme 'water-theory'—or indeed any other postulating that steam plays a necessary intermediary chemical rôle—that it may now be dismissed as one of those 'Phantoms of the Cave' arising (as Francis Bacon said) from "a fanciful Philosophy, which regards only a tew cases."

WILLIAM A BONE D. T. A. TOWNEND.

Imperial College of Science, South Kensington, London, S W 7, Dec 6.

# Sound Absorption Coefficients Measured by Reverberation and Stationary-wave Methods.

I have to correct the calculation of a reverberation coefficient of absorption given in my letter published in Nature of Dec. 3. Owing to a misprint in the paper from which I quoted (*Proc Roy. Soc*, 115, 418; 1927) the value of  $\alpha\Omega_2$  (the imaginary part of the acoustical admittance per unit area multiplied by the velocity of sound) for an experimental acoustic plaster was given as -0.0100, whereas it should have been -0.100. Also the factor  $(\Omega^2 + \Omega^2_2)$  occurring in the last term of the expression for the reverberation coefficient in terms of acoustical admittance should read  $(\Omega_1^2 - \Omega_2^2)$ 

The recalculated value of the reverberation absorption coefficient at 512 vibrations per second for the acoustic plaster is 0.37, which is very close to the reverberation coefficient quoted by Watson for 'Akoustolith,' namely, 0.36 For 'Akoustolith' itself I have found by the same method that the reverberation coefficient at 512 vibrations per second is 0.35.

E T. PARIS.

Biggin Hill, Kent, Dec. 6.

# A Change in the Refractive Index of Air when an Electric Glow Discharge is passing through it.

The change is studied by observing the shift in the interference fringes obtained by Jamin's plates. The change is purely local in the region of the luminous discharge. By varying the pressure inside the air-tube, it is found that the shift is a maximum at a pressure of the order of 2-5 cm. of mercury. Ionisation of the air by X-rays or by Tesla discharge does not cause any appreciable shift.

The shift does not appear to be due to any local changes of pressure. Whether it is purely a temperature effect is being studied. The shift was very small in the preliminary experiments, the maximum being only about a third of a fringe. A shift of two or three fringes has now been obtained and a higher

degree of accuracy is expected

J. B. SETH.

Physics Department, Government College, Lahore, Oct. 27.

## Jubilee of the Institute of Chemistry.

TUBILEES and centenaries, as they recur and pass, serve at least to make us look forward as well as backward, to envisage the probable extension of influence as well as to recollect the circumstances of the birth of some of our most familiar institutions The Institute of Chemistry has just celebrated its fiftieth birthday, as befits that age, in genial intercourse with the other members of the British branch of the chemical Fifty years is but a short life compared with the seniority which some corporate institutions have attained, but although it represents scarcely more than the passing of extreme youth it is, nevertheless, quite a respectable age when the modernity of the distinctive profession which it represents is taken into account. There was a time when chemistry was the spare-time accomplishment, so to speak, of the medical man or of the student of the diverse manifestations of Nature; now-so distinct are the details of their aims, their technique, and even their language—it is difficult enough for chemists of various tribes to find common ground in one another's interests. Yet all, as a unified but composite profession, are represented by this organisation; the works chemist, the public analyst, the consultant in metallurgy, in brewing, and other specialised branches, the instructor, the researcher, the professor, all meet within its fold

The Institute, however, does not serve merely the profession—It has been continuously active in the interests of the country, whose citizens have a very real interest in the maintenance of proper scientific control of its food, its beverages, its medicines, its manufactures; there is, in fact, scarcely any phase of our material interests which does not at some time or other come under the professional observation of chemists. That such control or examination should be adequate, and that the examiner should be highly competent and trustworthy in the exercise of his functions, briefly sums up the policy

of the profession.

The Institute of Chemistry of Great Britain and Ireland had its origin in a meeting, held in the rooms of the Chemical Society on April 27, 1876, to discuss the organisation of the chemical profession. Prof. Abel was in the chair A committee with Mr. (afterwards Sir) Walter Noel Hartley as secretary was appointed to confer with the Chemical Society, and as a result of their deliberations it was resolved to form a new association, to be entitled "The Institute of Professional Chemists of Great Britain and Ireland," with Prof. (later Sir) Edward Frankland as its first president; the present title was, however, adopted in deference to official representations. It appears to have been in Sir Edward Frankland's mind that the idea of such an institution was formulated at a dinner given in honour of Cannizzaro on May 31, 1872, when he expressed his conviction of the necessity for the creation of some such body as would correspond with the Royal Colleges of Physicians and

Surgeons, the Institution of Civil Engineers, and the Inns of Court

The new Institute was incorporated by licence of the Board of Trade under the provisions of Section 23 of the Companies Act, 1867, on Oct. 2, 1877, and was afterwards incorporated by Royal Charter on June 13, 1885, with authority to grant certificates of competency, and to register persons qualified to The membership roll now includes more practise than 5300 fellows and associates, and 800 students In recent years it has been found desirable to establish local sections, in order to facilitate intercourse between the members, and to provide opportunity for the discussion of matters of professional interest Local sections have thus been established as follows: Birmingham and the Midlands, Bristol and South-Western Counties, Edinburgh and East of Scotland, Glasgow and West of Scotland. Huddersfield, Irish Free State, Leeds Area, Liverpool and North-Western District, London and South-Eastern Counties, Manchester and District, Newcastle-on-Tyne and North-East Coast, Northern Ireland, South Wales, Cape of Good Hope, Malaya, and New Zealand, and honorary corresponding secretaries have been appointed to act throughout the Empire.

The patron of the jubilee celebrations is HRH. the Prince of Wales, KG; the present president of the Institute is Prof. Arthur Smithells, who is the seventeenth occupant of the presidential chair. The affairs of the Institute are in the hands of the president, six vice-presidents, a treasurer, and thirty-nine councillors, who number among them many of the names most honoured in the profession Mr. Richard B. Pilcher holds the office of registrar and secretary; parenthetically, Mr. Pilcher has a deserved reputation for an encyclopædic knowledge

of professional matters.

In the forefront of the Institute's work is the maintenance of a high standard of training and proficiency among members of the chemical profession. In this matter it does not intrude upon, but supplements, the work of the university and the technical college. It is not a training centre, but an examining body, particularly in certain specialised branches of vocational chemistry. Institute recognises the hall-mark of the university by admitting first and second class honours graduates, under appropriate conditions, to the associateship without further examination; in order to qualify for fellowship it is necessary to pass a searching examination in one of the seven branches, namely: inorganic chemistry, physical chemistry, organic chemistry, biochemistry, the chemistry and microscopy of food, drugs, and water, agricultural chemistry, and industrial chemistry. The examinations, if not held at distant centres, take place at the Institute's own laboratories, which, together with the council room, hbrary, and administrative offices, are located at 30 Russell Square, London, W.C. The Institute was formerly housed at 30 Bloomsbury Square. W.C; on the expiration of the lease of these less convenient premises, a fund was raised by private subscription among members and others, and the present building was erected in 1914–15

Another side of the Institute's activities is concerned with the maintenance of a strict code of professional conduct, with professional status, and matters germane to appointments in the public service. An appointments register is largely used by members and prospective employers, and a benevolent fund has been instituted so that temporary assistance can be given in case of need. The usefulness of the Institute is also apparent in the organisation, both at headquarters and at local sections, of lectures on matters of professional interest, and in the publication of 'Official Chemical Appointments' (a directory) and the registrar's useful guide entitled "The Profession of Chemistry." "Chemistry as a Career" is the title of a booklet containing a synopsis of lectures given by the registrar before college chemical societies during 1921-23 These books convey a warning as well as encouragement, for they clearly indicate that only a certain type of mind or personality can hope to attain even minor eminence, that material rewards are seldom of the richest and often of the poorest, and that real devotion to the spirit of service and inquiry is both expected and exhibited

Although the variety and importance of the services which the chemist renders to the community are even now but inadequately realised, the Institute of Chemistry has thus done much to define, to explain, and to improve his position in both public and private practice, it has equally endeavoured at all times to assist His Majesty's Government in matters on which chemistry has a bearing, and in return the work and qualifications of the Institute have been in a large measure recognised by the State At the time of its foundation, few universities and colleges provided satisfactory preparation for the profession of chemistry; indeed, it is difficult to realise what the position to-day would have been had this contribution to the development of systematic chemical education been withheld, and had no attempt been made to bring together in one body those who practise in a calling which is now acknowledged to be so vital to the progress of the civilised world. The strength and the future influence of the Institute will be fostered by the continued loyal co-operation of its fellows and associates in the maintenance of their own status and in the protection of such of the interests of humanity as are specially within their knowledge

## Belief and Evidence in Water Divining.

By Dr. Hugh Robert Mill.

T the Public Works, Roads, and Transport Congress recently held in the Agricultural Hall, Islington, the subject of water divining was introduced by Prof J. W. Gregory, who read a paper setting forth the admitted facts and stating his own reasoned judgment with the candour and conviction of an experienced man of science sure of his ground and satisfied with his conclusions So frankly did he acknowledge the widespread popular faith in the use of the divining-rod as a means of finding water that the writer of a leading article on dowsers and doubters in the Times of Nov. 25 appears to class him amongst the believers. Prof. Gregory, however, developed the case against the dowser with a convincing moderation and clarity of reasoning, and in the issue of Dec. 2 he stated that his paper showed "that the evidence of all the controlled experimental tests in England of which I know is against water or oil . . . divining."

This important paper may be summarised as follows. The literature of the subject is enormous, and Prof. Gregory, who appears by his citations to have been exceptionally well read in it, does not claim to have read one-hundredth part of what has been written. He relies largely on the recent book on the divining-rod by Sir William Barrett and Mr. Besterman, but brings much personal experience to supplement it. He points out that while at one time the expenses of a water-diviner employed by a public body were surcharged on the members, recent decisions have allowed the cost to be met from public funds, and a diviner

has even been employed in the crypt of St Paul's Cathedral to seek for the water channels below the foundations

The cause of the movements of the divining-rod may be explained in one of three ways (1) by fraud and practical jokes, (2) by unconscious imposture; (3) by some actual force which acts on the rod directly or indirectly. This third view Prof. Gregory was at one time inclined to share, believing that the diviner might possess some idiosyncracy in virtue of which he might be affected by slight sharply contrasted differences of moisture in the atmosphere, but he abandoned it because it would not explain the response of the divining-rod to things other than water, and would not account for water-diviners obtaining results in rain; moreover, it was dismissed as improbable by three eminent physiologists whom he consulted.

There are three rival lines of explanation: (1) that the rod responds to some physical stimulus, possibly allied to radioactivity, as upheld by M. Henri Mager As such matters were remote from Prof Gregory's own province he submitted Mager's book "Les Baguettes" (1920) to Prof. Desch, who found that its arguments did not furnish any support for the view that the diviners have any powers of detecting water or minerals. Mager's claims were also dismissed as extravagant and absurd by the U.S. Geological Survey; (2) that the movement of the rod is due, though perhaps unconsciously, to the diviner. This is the view elaborated by Barrett and Besterman, who

which is a second

dismiss the evidence for an external physical force by arguments which seem unanswerable claim is that the diviner has a sort of second sight. the evidence for which is on a par with that brought forward by spiritualists for their alleged clairvoyance; (3) that the diviner unconsciously or subconsciously moves the rod owing to an impulse due to unintentional suggestion from the bystanders or by his recognition of indications favourable for water. The process of subconscious movement of the rod by the dowser is explained by Dr Millais Culpin in his "Spiritualism and the New Psychology" (1920), as an example of the dissociation of the various streams of activity which flow side by side in the human brain, and Prof. Gregory considers that some of the best dowsers, like Mullins, probably act by this process, giving expression to the results of long experience or special quickness of perception of signs of water at the surface

Prof Gregory goes on to examine the evidence as collected in Barrett and Besterman's book in order to determine which of these conflicting explanations is the most reasonable, and he deals in turn with a series of experiments on which the authors of that book relied as examples of the triumphs of the dowsers over the geologists as water finders. His decision is that the happy selection of the sites in the four cases considered was in accordance with common sense and did not require cryptæsthesia. He cites a number of independent tests of the powers claimed by waterdiviners, and shows that both geological surveys and individuals have on many occasions proved the madequacy of the claims made. Similar tests with regard to dowsing for mineral oil were equally negative. It is pointed out that testing the divining-rod is difficult and promises no answer that will be universally accepted because the claims of different diviners are so contradictory and elusive that any test may apply only to the individual tested, and perhaps to him only on a particular day. It is pointed out that in the case of the Abbé Paramelle, claimed by Barrett and Besterman as a diviner who did not use a rod, the Abbé's own explanation that he found water by studying the indications of the surface is perfectly satisfactory.

As regards the nature of divining, Prof. Gregory says that the successful water-diviner is probably a quick observer who has usually had considerable experience in the search for water, and as he goes over the ground he probably recognises clues to the presence of underground water which subconsciously lead to movements of the strained muscles of the hands holding the rod In some cases such an experienced dowser will probably score no higher a proportion of successes than a competent geological expert would do, while in other cases the reputation of the diviner is made by lucky coincidences which are remembered and exaggerated while the failures are forgotten. It is concluded that although the claims of the divining-rod are invalid, an expert diviner may be useful under some conditions.

The outcome of Prof. Gregory's discussion seems to be that the use of the divining-rod is a survival of primitive magic, and that there is no reason to suspect the existence of unrecognised properties of matter or power of mind from the experiences and From the point of view performances of dowsers of the geologist it seems both reasonable and right to decide that further investigation of the diviningrod is waste of time and that his special knowledge can be of more service to the advancement of science if applied in other directions Nevertheless, there are other points of view, and recent advances in physical and psychical science may enable a keen and cautious investigator to reach some more positive conclusion than the evidence now available justifies. Instead of taking as the subject of study the exploits of the expert dowser who has an axe to grind, or of the amateur enthusiast who has a theory to uphold, might it not be better to try some simple person who, while not using it for pay or reputation, is possessed of the gift—if gift it be—of finding a divining-rod turn in his hands in the neighbourhood of underground water?

Stress is usually laid on the erratic or even contradictory results of many of the experimental tests which have been made, as opposed to the certain and repeatable results of scientific demonstrations. But scientific demonstrations of this kind only become possible when all the conditions are known and are under control Is this yet possible in the measurement of perception? If not, may not indications be found sometimes which indicate true relationships, though on a second attempt the demonstration may fail utterly? Every listener to distant broadcasting stations knows that for a week at a time he may pick up Cork every night and fail to find Belfast once, whereas at another time, though using exactly the same settings and the same battery strength, he may hear Belfast every evening and never get Cork at all. My view is that the facts which have been proved as to water divining are deserving from the strictly scientific point of view of as full and specialised attention as are the facts relating to electric waves. It would be very satisfactory if it could be established that Prof. Gregory's belief is correct and that the waterdiviner succeeds by his quick, even if unconscious, recognition of surface signs that may escape the ordinary observer. It would be equally satisfactory if it could be shown that the nervous system is capable of detecting radiations of a different frequency from those of light and heat, and that water, and perhaps other substances, may emit such radiations at ordinary temperatures one suggestion does not seem to be intrinsically more improbable than the other. The research would of course be very difficult, and the first-class minds which alone could pursue it to a satisfactory conclusion can probably devote themselves to much more productive investigations at the present time.

If there is anything in these phenomena, the discovery will undoubtedly be made in the fullness of time, possibly many years hence; but meanwhile,

it is at least satisfactory to find that attention is being paid to things which are involved in such baffling perplexity that the easiest course is to look the difficulty steadily in the face and pass by. When the investigator emerges who is able and willing to tackle the problem, he must not be afraid of finding results which his present knowledge may lead him to think as absurd as the properties of radium seemed before they were discovered

In the course of correspondence in the *Times*, induced by the article on dowsers and doubters already referred to, Mr A. A Campbell Swinton outlined in the issue of Nov 30 a scheme of m-

vestigation which he suggested might be taken up by the National Physical Laboratory He proposes the construction of an underground channel through which a controlled supply of water might be allowed to flow or percolate in such a manner that the fact of sensitiveness to the presence of water could be tested and, if found, the rate of transmission of the impulse from the water to the dowser might be measured. If this suggestion were acted upon, a committee, which would satisfy both the credulous and the sceptical, could no doubt be brought together to arrange details of the tests

## The Use of Radio-Elements as Indicators.1

By Prof. FRITZ PANETH.

THE use of radio-elements as indicators is a special chapter of radioactive investigation, which differs from the topics usually treated under the name of radioactive research, in so far that the radio-elements are here not the object of the study, but are used as a mere agent in the solution of problems which in general have nothing to do with radioactivity at all. These problems may be found in very different branches of chemistry, physics, and even biology, and it is to be expected that radio-elements as indicators will be more used the more familiar the advantages of this method become to non-radiologists.

Only an elementary knowledge of the principles of radioactivity is necessary in order to understand and even to apply the method. It is based upon the extreme sensitivity of radioactive measurements, and upon the chemical relations of the

radio-elements to ordinary elements.

As to the first point, it is well known that by help of an electroscope, invisible and imponderable quantities of radioactive matter can be detected and exactly measured. From the radioelement thorium C, for example, which can very frequently be used as an indicator,  $10^{-17}$  gm. allows for exact qualitative and quantitative determination. Now thorium C is 'isotopic' with ordinary bismuth. Since isotopes show identical chemical properties, it is possible to substitute the radio-element for its inactive isotope, and to acquire information concerning the element in extremely dilute solutions. The chemical behaviour of bismuth may thus be elucidated by a study of thorium C. In certain cases it is found advantageous to mix a certain amount of the radioelement with a sample of the inactive element in order that an otherwise indeterminable fraction of the original quantity may be detected or determined electroscopically. Instances in which such minute fractions of an element have been separated by some such process as diffusion, solution, or volatilisation, are discussed below. By choice of the appropriate ratio between the quantities of inactive element and radio-element in the sample, it is possible to cover the entire range of mixtures from those detectable only by means of the electroscope to those containing readily weighable amounts of material.

In selecting a radio-element for use as an indicator, it is generally desirable to find one that may be detected in very small amounts. It must be borne in mind, however, that the half-value period (T) varies inversely with the intensity of radiation, and that an element detectable in small quantities invariably has a short half-value period. It would therefore never be feasible to employ radium C'  $(T=10^{-7}\ {\rm seconds})$  or thorium C'  $(T=10^{-11}\ {\rm seconds})$  as indicators. Even the three indicators available for the element thallium are too shortlived for a number of experiments.

For this reason it is not practicable to use all of the elements included in the well-known lists of radioactive isotopes for the present purpose. Only the elements named in the following table can find practical application. Those to be recommended

most highly are underlined in the table.

Even radio-elements such as ionium, uranium  $X_1$ , and uranium  $X_2$ , which possess no inactive isotopes, frequently are of service in increasing the radioactive intensity of their longer-lived, less active, and therefore less readily detectable radioactive isotopes. Uranium  $X_1$ , for example, is mentioned in the table as a satisfactory indicator for thorium. So also, thorium X may be used as indicator for radium, and radium A for polonium. But radium and polonium themselves may in a broader way be employed as indicators in certain lines of work. For, in the narrower sense, the function of the radio-elements 'as indicators' may be conceived to be restricted to those experiments in which the radio-elements are substituted for their active or inactive isotopes. In the broader sense, however, this function may be extended to cover any procedure in which the radioelement is used as an instrument in the detection, determination, or investigation of matter in minute quantities.

A brief account of some examples, where radio-

<sup>&</sup>lt;sup>1</sup> From an address delivered to the Bedson Club, Newcastle-upon-Tyne, on Mar. 17, 1927. A fuller discussion of the subject in English by the same author, with references to the literature, will shortly appear in Volume 2 of the Baker Lectures, delivered by non-resident lecturers at Cornell University (Ithaca, N.Y). For literature, see also G. Hevesy and F. Paneth, "Manual of Radioactivity" (Oxford, 1926).

elements have actually been used with success as indicators—rather than an abstract discussion of possible applications of this method—may help to a fuller understanding

From the large number of experiments with radio-elements as indicators in the field of analytical chemistry, the choice of one typical case may well suffice. The solubility of lead chromate at room temperature is too small to admit of accurate determination by simple gravimetric methods. It is of course possible, in cases of this sort, to make use of conductivity measurements, or to calculate the solubility product from the equilibrium constants. With concentrations as low as that of the

RADIOACTIVE INDICATORS.

Element	Indicator				
Thallium	Radium C' Thorium C'' Actinium C''	T = 1 32 m $3.20 m$ $4 76 m$

saturated solution of lead chromate, however, either of these methods would entail a lengthy and delicate investigation. With the aid of a radioactive indicator, on the other hand, the solubility of lead chromate may be measured with no more difficulty than that involved in a simple weighing.

To a definite amount of a soluble lead salt, a known quantity of thorium B is added. The activity of this preparation may be measured in any desired units, as, for example, the number of scale divisions per minute on the particular electroscope used. If, for example, 10,000 units of thorium B is thoroughly mixed with 10 milligrams of lead, it is apparent that one unit of thorium B will invariably indicate the presence of 0.001 milligram of lead. From the artificially activated lead thus obtained it is now possible by the usual chemical methods to prepare the chromate. After

the saturated solution of this compound has been held at the desired temperature in a thermostat for a sufficient time, its composition may be ascertained by evaporating a few cubic centimetres to dryness, and measuring the activity of the wellnigh invisible residue in the electroscope. (This example is treated in more detail because the general procedure is typical also of the following cases)

Had the radio-elements been available for use as indicators during the last quarter of the nineteenth century, one extremely important service might have been rendered with their aid, to the then newly advanced theory of electrolytic dissociation. Proof of the actual fact of dissociation, and of the interchange of ions, is readily obtainable with the help of the radio-elements, mixed, in accordance with the procedure just outlined, with their inactive isotopes It is possible to demonstrate in this way the fact that the particular atoms or radicals assumed to be liberated by electrolytic dissociation do not retain their places in given molecules, but are free to move back and forth from one place to another. If, for example, equimolecular amounts of an mactive lead chloride and a radiochemically sensitised lead nitrate in aqueous solutions are mixed together, and the lead chloride is allowed to crystallise again, it will be found that the active lead atoms are distributed proportionally between chloride and mtrate, and must therefore have migrated in solution from lead nitrate to lead chloride until the kinetic equilibrium has been

Radio-elements have further shown their utility in connexion with measurements of the surface of powdered adsorbents. concerning the extent of surface is obviously necessary in deciding whether the adsorbed layer is of the thickness of one, or of more than one molecule. This question has been answered in various ways by various theories of adsorption Particularly in the case of powders, which, because of their greatly extended surface, are preferentially used as adsorbents, determinations of superficial magnitudes have hitherto been unsuccessful. If the choice of materials be limited, however, to solid compounds of elements possessing a known radioactive isotope, a safe and simple method becomes available. It is based upon the fact that the radio-element, added to the saturated solution of the isotopic adsorbent, becomes in a very short time equally distributed between the molecules of the dissolved part of the adsorbent and those of the uppermost layer of its crystalline surface. In this way the extent of the surface can easily be computed from the decrease of the radioactivity of the solution. The surface of the sulphate and sulphide of lead, of the phosphate of bismuth, and so on, have thus been measured, and with these values it has been able to establish the fact that on all these adsorbents the limit of adsorption is reached as soon as a layer of one molecule in thickness has been formed.

From the chemistry of inorganic preparations, the discovery of the volatile hydride of bismuth

with the help of its isotopic radio-elements may be mentioned From many fruitless investigations it had to be concluded that this compound, if it could be prepared, would be obtained only in very minute fractions of the initial material, and might therefore easily escape detection by the usual The apparatus for measuring methods of analysis radioactivity can, however, be selected so that a ten-millionth part of the bismuth in the original material will give a product recognisable with certainty, both qualitatively and quantitatively This wide extension of the range of measurement is quite necessary if the condensation and re-volatilisation of bismuth hydride are to be detected, its mere existence can be proven by relatively simple means and even by a lecture experiment Decomposition of magnesia turnings, covered with thorium C or radium C, by dilute hydrochloric acid, yields the volatile hydrides of these radio-elements, which can be condensed at the temperature of liquid air and—on the other hand—decomposed and measured in a heated glass-tube After experience had been gained with the radioactive method described above in the study of the best method of preparation, and of the stability of bismuth hydride, it was found possible later, with comparatively little difficulty, to prepare this compound also from inactive bismuth, making use of magnesium as before in the preparation of the hydride. It may be mentioned that the amount of material by which the existence of the compound was first recognised was but 10<sup>-15</sup> gram, and that it was found possible, with further increase in the sensitivity of the process of detection, to establish by the use of radioactive indicators the existence of a gaseous lead hydride formed in still smaller amounts. Here also the radioactive test was a spur to ultimately successful experiments with ordinary lead.

That radioactive indicators might occasionally serve to advantage in technological research can scarcely be doubted, even if they have been more frequently applied hitherto to scientific problems. A question of this type is that of testing rubberised fabrics for their permeability to gases. When, during the War, in connexion with the choice of suitable samples of material for gas masks, the task of determining numerically the permeability to gases of the materials submitted by different firms was assigned, it was found convenient to employ, as a test gas, air with which was mixed a trace of radium emanation (radon). The fractional portion of the gas which penetrated the material under investigation could then be determined electroscopically.

A considerable number of problems in physics can be brought to solution through the agency of radioactive indicators. Among these, the experimental study of 'self-diffusion' is of paramount importance. By this is understood the phenomenon, expected from the kinetic theory of matter, that the atoms of a homogeneous gaseous or liquid element move among one another under the same law that applies in the case of a diffusion of one element into another. Since in self-diffusion, how-

ever, the external properties of the element in question remain entirely unchanged, it has been possible to carry out this process hitherto only as an imaginary experiment, of which indeed Maxwell and Boltzmann have made frequent use G. Hevesy, the author of many experiments with radioactive indicators, has succeeded in bringing self-diffusion within the scope of observation prepared and sealed in a hard glass tube, a fused cylinder of lead, of which three-fourths was ordinary lead and one-fourth activated lead, thorium B was used as radioactive indicator in experiments of only short duration, while the long-lived radium D was chosen for more extended experi-If now the lead in the tube is cautiously melted, and is held at this temperature for several days, it is easy, after solidification, to measure the distribution of the activity that has taken place within the lead column during the period of the experiment. In this case, therefore, marked lead atoms have diffused among other lead atoms, and the self-diffusion constant can be calculated by the usual methods.

Among other applications to physical research which can only be mentioned here, are the formation of various alloys at low temperatures, the speed of solution of very thin layers, the rate of evaporation in relation to the amount of liquid to be evaporated, and diffusion in ideally dilute solutions.

Since bismuth compounds of very diverse composition have recently been investigated from the viewpoint of therapeutics as a substitute for arsenic, it was of interest to physiologists to learn in what proportions the bismuth introduced is stored up in the different organs of the body, and is eliminated in the urine and fæces. Since small amounts only are involved, the determination can best be accomplished by the radioactive method. Radium E was employed as indicator for bismuth in place of thorium C, in view of the fact that the experiments extended over a period of several days It was mixed with the bismuth preparations and injected intra-muscularly into the guinea-pigs employed in the experiments The products of excretion were ashed and measured electroscopically, and after the end of the experiment the organs of the animals were similarly treated One conclusion to be drawn from the chart showing the exact distribution of the bismuth, is that the accumulation of this element takes place chiefly in the kidneys. Analogous experiments with lead preparations show that absorption takes place chiefly in the liver. The absorption and distribution of lead in roots, leaves, and fruits of a plant (Vicia faba) were investigated in a similar wav.

The examples of the use of radio-elements as indicators here presented may suffice to show that the method thus illustrated is capable of many-sided application. It is to be hoped that in the future a greater number of chemists and physicists than heretofore may make use of the method, and may thereby facilitate materially the solution of many problems.

## Obstuary.

### Prof. K D. Glinka.

SOIL students in all parts of the world will learn with deep regret of the death of Prof K D. Glinka on Nov 2 He had for some time been in failing health and had felt some heart strain, but none of those who met him last June and July at the Soil Congress in the United States had any suspicion that he was so near the end. All who attended were prepared to accord him their deepest respect for his profound knowledge of the subject and his own brilliant work and though they were with him but a very short time, his unfailing courtesy and his kindly good humour had endeared him to everyone who met him

Glinka was born in 1867 in Smolensk, the son of one of the most ancient and honoured aristocratic families of the old regime in Russia 1 He studied first at the University of St. Petersburg, which he left in 1889, and afterwards at the University of Moscow, where he obtained his doctor's degree in mineralogy. In 1900 he was appointed professor of mineralogy and geology at the Agricultural Institute of Novo Alexandria in the Government of Lublin, which since the War has again become Polish territory, and has therefore resumed its old Polish name Pulawy: the Institute, under this name, has now become the central agricultural experiment station of Poland . Within two years of his appointment he was, at his own request, and in consideration of his studies on soil, transferred to the chair of pedology at the same institute. Between 1908 and 1914 the Emigration or Settlement Board of Russia arranged a series of expeditions to study the soils of Russian Turkestan, putting Glinka in general charge; this, however, did not necessitate his giving up his professorship. He made the big expedition of 1909, travelling from Kabousaya to Vernogo, thence through Lepsinsk to Sergiopol, and finally Semipalatinsk. The material collected in this and the other expeditions was worked up by the Dokuchaiev Pedological Committee. Reports were issued in his name from 1908 to 1914: a general summary is given in Russian and German in La Pedologie, 1912, vol. 14, pp. 43-63 He became president of this Committee in 1912, and relinquished the chair at Novo Alexandria; in 1913 he went to the Agricultural Institute at Voronesh, the soils around which he studied: in 1922 he returned to Petrograd as director of the Agricultural Institute: this post he was holding at the time of his death

Glinka was essentially a field worker, studying the section or profile of the soil from the surface to a depth of some six or eight feet His methods are well illustrated in his paper "On the So-called Brown Earth," which appeared in La Pedologie, 1911, vol. 13, p. 17 (Russian and German)

had an amazing capacity for seeing things in a soil section that ordinary workers miss: the present writer had numerous opportunities of admitting Glinka's superiority as an observer during the Soil Excursion in the United States last summer. Glinka himself did but little laboratory work on soil, but his marked ability to use the results of others is illustrated in his studies of the differences between podsols and peaty soils, published in

La Pedologie, vol 13, p. 1.

In 1914 Glinka's book "Die Bodentypen" was published in Berlin, unfortunately its value was not at first recognised by British students, none of whom had at that time any adequate knowledge of the Russian soil work. It was not until the International Soil Conferences were resumed that this defect was remedied, now the Russian work is accorded full recognition, and some of the presentday investigators not only use Russian terms for the soil groups, but are also studying the Russian language in order to read papers that are not translated

The chief difference between the Russian and the British soil work is that the latter has been chiefly directed to the study of the soil as a medium for plant growth, while the Russians have studied the soil as a distinct natural object without regard to questions of fertility The difference arose from the circumstance that the early fertiliser experiments at Rothamsted and elsewhere had given striking increases in crop production, while those in Russia had not. The British workers therefore concentrated on soil fertility, which they were learning to control: the Russian workers took another direction. These studies began soon after 1861, when the serfs were emancipated by the Tsar Alexander II. The Free Economical Society was formed, and arranged with D. L. Mendeléeff, then a young man, to carry out fertiliser experiments in various parts of Russia. These experiments failed to give the definite positive results obtained m England and elsewhere, and Mendeléeff discontinued the work and returned to pure chemistry to discover the Periodic Law It is interesting to speculate what might have happened in the history of science had the fertiliser experiments come out more definitely and Mendeléeff become an agricultural chemist. Later on the Society arranged with V. V Dokuchaiev to study the chernozem—the black earths of Russia, on which wheat is so much grown.

Had this investigation been made in England, it would almost certainly have resolved itself into a study of the crop-producing power of the soil; in Russia things happened otherwise, and Dokuchaiev, disregarding relationships to plant growth, studied only the soil itself, and discovered the existence of layers more or less parallel with the surface and all related one to the other. Over considerable areas of Russia he and his pupils found similar morphological characteristics, on the basis of which, rather than of geological origin, they

¹ By a curious enor in journals m, for which it is difficult to account, one of the best American daily papers, in dealing with the Soil Congress, described Glinka as the son of a peasant — This description was copied in other papers and read out at certain of the functions, much to his amusement.

classified the Russian soils P A Kostychev studied these relationships chemically. A close connexion was found between the soil types and climate, and the generalisation gradually emerged that the soil is largely a function of the climate, this being more important than the parent rock

This remains the fundamental thesis of the Russian workers If the climate be known it is possible to predict what the soil type will be. Further studies have revealed discrepancies which, however, are courageously dealt with, where it is not possible to explain the soil on its presentday climate, as in the case of the so-called degraded chernozem, a change of climate is postulated to The British soils account for the observed facts present considerable difficulties, many of them being so closely dominated by the properties of the parent rock that the geological classification is still the best, but they are being studied by the Russian methods It is now universally recognised that the Russian pedologists have added much to the resources of soil science, and among the foremost of the pioneers Glinka's name will always be counted. E. J. Russell.

## LORD KENYON, K.C.V.O.

LORD KENYON of Gredington, Flintshire, who died on Nov. 30, aged sixty-three years, was a country gentleman with a fine record of public service in respect to agriculture and Welsh institutions such as the University and the National Museum of Wales. He was Lord Lieutenant of Denbighshire, and had been Lord-in-Waiting to three sovereigns.

The first Lord Kenyon of Gredington was the great jurist; the late peer, the fourth holder of the title, succeeded his grandfather in 1869 at the age of five. He was educated at Eton and Christchurch, Oxford, and was created K.C.V.O. in 1907. His interest in agriculture led to his appointment when a young man as a member of the Welsh Land Commission. In 1924 he was chairman of the Advisory Committee on Milk Production and of

the Agricultural Wages Board.

As Pro-Chancellor of the University of Wales, Lord Kenyon did a great deal to foster and encourage scientific research in the University. He realised very clearly that one of the chief aims of a university must be the attainment of truth and the extension of knowledge. He took a particular interest in the new science buildings at the University College of North Wales, Bangor, which were opened in 1926, and in the well-equipped laboratories which have been set up at Swansea during recent years. He also watched with growing interest the rise of the new physics and chemistry buildings at the University College of South Wales and Monmouthshire, Cardiff, which are at the present time nearing completion. His great mterest in the Welsh National School of Medicine was largely due to the fact that he realised the great services that by means of scientific research and investigation such an institution is capable of rendering not only to the solution of health prob-

lems in Wales, but also to the cause of medical science generally. For this reason he was a strong advocate of what is known as the 'medical unit system.'

Few realised more clearly than Lord Kenyon the function of a university in the life of the community, as a place for guarding and increasing our inheritance of knowledge and for keeping that knowledge alive. He was a great believer in postgraduate scholarships for research, and nothing gave him greater pleasure than to announce gifts made from time to time for the endowment of such scholarships. He secured many such gifts for

the University of Wales

Lord Kenyon's services to the National Museum of Wales at a critical period in its development He was elected president were no less valuable of the National Museum for the five-year period which terminated on Sept 30 last. Though he had had no previous connexion with the institution, he at once set himself to grasp the problems and needs of the Museum and threw himself heart and soul into its work. When he took office, only the western wing of the Museum building in Cathays Park, Cardiff, was in use The great part of the south front was a mere shell, and there was at that time no possibility of finishing it. He was foremost in urging on all interested in education in Wales that the completion of a sufficient portion of the building adequately to illustrate the environment and history of man in Wales, and the achievement of the people of Wales in the arts and crafts, was vitally important. Generous benefactions having enabled this work to be carried out, it fell to Lord Kenyon, as president, to receive their Majesties the King and Queen on the occasion of the opening ceremony in April last, and it is a source of great gratification to all concerned that he should have been able, before his death, to see this national institution happily launched on its career

Lord Kenyon proved an admirable president; he never spared himself in the services of the Institution, and attended every meeting at which his presence was desired, even at great personal inconvenience. Though the intra-mural work of the Museum was his chief interest—his personal inclinations leant towards art and archæology—his long experience of administration and of Welsh life and culture, led him to support in the warmest possible way the efforts made to extend the extramural activities of the Museum by the scheme successfully launched during his presidency of affiliating to the Institution the local museums in

Wales

Lord Kenyon's imposing figure, charming manner, and unfailing courtesy endeared him to all classes of the community. By his death Wales loses one of her most conscientious, painstaking, and influential public men, who combined the prestige of a great name with an exceptional personality. In the words of one who knew him well: "He brought to the service of the Welsh people the qualities which in the past made leadership easy and natural to aristocracy."

### News and Views.

At the Savoy Hotel, London, on Dec. 10, a private demonstration of a new musical instrument was given by the inventor, Prof. Leo Theremin, of the State Institute of Technical Physics, Leningrad. The apparatus, designed for "drawing music from the ether solely by free movement of the hands in space," proved to be a loud-speaker connected with a thermionic valve circuit which included a metal rod, the electrostatic capacity of which is altered by the proximity of the performer's hand, the whole arrangement being an application of the familiar 'howling' of a badly adjusted broadcast receiving set when the hand is brought near to the tuning condensers. The intensity of the sounds is controlled by varying the position of the other hand in relation to a metal hoop. or varying the pressure of the foot upon what appeared to be a disc of carbon For notes near the middle of the musical scale, the hand is at a few inches from the rod and a change in this distance of an inch or so alters the pitch of the note by a tone, the whole range being apparently about an octave. Faulty intonation occurs, therefore, unless the performer judges accurately the required distance from the rod for the desired frequency of oscillation. Wide variation of tone quality was shown to be producible, but the demonstration was limited to the performance of slow vibrato melody only. Prof. Theremin's apparatus is an ingenious application of well-known electrical effects, and it evidently possesses possibilities of development as a musical instrument, though of course harmony cannot be produced by it.

The discovery of a large area of nitrate, 120 miles east of Alice Springs, the administrative centre of the new territory of Central Australia, has been confirmed by Sir Douglas Mawson, who has visited the locality. The existence of the nitrate was indicated by the report of an aboriginal that the earth ignited when thrown on the fire. Sir Douglas Mawson identifies it as potassium nitrate, and its value is estimated as from £60 to £90 a ton. Potassium nitrate occurs naturally in Bengal, where it is formed by the decomposition of excreta in the presence of nitrifying bacteria. Potassium chlorides occur in basins and in arid areas by the evaporation of waters which drain from rocks rich in potash. The new Australian deposit may have been formed in a basin by the decomposition of the animal remains in swamps This discovery justifies the recent decision to extend the railway from Oodnadatta, the present northern terminus of the South Australian railways, to Alice Springs, and will probably lead to the completion of the long-projected and promised railway from South Australia across the centre of the continent to the Northern Territory.

The retirement of Dr. L O Howard, Chief of the Bureau of Entomology, U.S Department of Agriculture, took place on Oct. 17 last. After graduating from Cornell University, Dr. Howard joined the Department of Agriculture in 1878 and became Chief of the Bureau of Entomology more than thirty-three years ago. We are glad to learn that his retirement

does not involve cessation of his entomological activities, and that he will now have opportunity to carry out researches for which his official life afforded him so little leisure. His frequent visits to Europe and his extensive travels upon that continent have made Dr. Howard one of the most familiar figures at congresses, and probably no living entomologist is more widely known personally among his fellowworkers. His unpretentious office in the Bureau of Entomology at Washington has for many years been the Mecca of all entomologists who have visited the continent of North America. In his earlier days he was well known as a leading authority on the Chalcidoidea, but as the years went on he exercised a wide influence on many branches of entomology in his His influence on the subject executive capacity extends far beyond the United States, and one of his greatest aims has been to further the interchange of ideas between men of diverse nations. Dr. Howard carries the good wishes of entomologists throughout the world on entering his retirement.

Dr. C. L. Marlatt, who succeeds Dr. Howard as Chief of the US Bureau of Entomology, is a graduate of the Kansas Agricultural College and an administrator of wide experience. He has for many years been associated with the U.S. Department of Agriculture, and for the last five years has been associate chief in charge of the executive work of the Bureau of Entomology. Dr. Marlatt is the author of a number of official bulletins of the Bureau, and was instrumental in the drafting and administration of the Plant Quarantine Act of 1912 He also holds the position of chairman of the Federal Horticultural Board.

On Dec. 23 occurs the centenary of the death of Robert Woodhouse, the Cambridge mathematician, who was successively Lucasian and Plumian professor and was also the first director of the Cambridge Observatory. Born at Norwich on April 28, 1773, the son of a linen-draper, Woodhouse was educated at the Grammar School, North Walsham, and entered Caius College, Cambridge, in 1790. He took his degree in 1795, being Senior Wrangler and Smith's prizeman, and was made a fellow of his College. His services to mathematical studies at Cambridge have often been commented on. Ball refers to him as "the apostle of the new movement," while Peacock said that his "Elements of Trigonometry" contributed more than any other book to revolutionise mathematical studies in Great Britain. He is entitled to the entire credit of introducing the calculus into England, and his efforts were ably seconded by Babbage, Peacock, and Herschel, who formed an Analytical Society, with the object of advocating the general use in the university of analytical methods and of the differential notation. Woodhouse died at the age of fifty-four years and was buried in the Chapel of Carus College.

In his presidential address to the Newcomen Society on Dec. 7, Mr. J. W. Hall dealt with the history of the making and rolling of iron. Starting with the Middle Ages, when iron was more expensive than lead, costing

more than £100 a ton, he traced the various improvements in the making of iron down to the present time The output for centuries was very small and, even in the middle of the eighteenth century, the production for the whole of Great Britain was but 250 to 350 tons per week. With the introduction of Cort's process of 'dry' puddling on a sand bottom in a reverberatory furnace, iron could be produced in larger masses, and Cort showed for the first time how bars could be produced entirely with the use of pit coal All iron was worked under the hammer, but for small rods recourse was had to the 'slitting mill.' Sheets and bars of lead, tin, and copper were rolled long before iron bars, and the first iron rolling mills simply finished to size bars previously hammered to form and dimensions The merit of Cort's second invention was that he reduced the raw iron in a series of rollers with gradually decreasing grooves, and laid the foundation of the existing methods. The address abounds in references and extracts from authors of the past and is a valuable summary of the technique of a most important industry.

WE have received from Messrs. Lever Brothers, Ltd., Port Sunlight, Cheshire, samples of their new vitamin products, 'Essogen' and 'Advita.' The former is a concentration of vitamins A and D in a neutral oil, and the latter is a concentrate of higher potency put up in capsules. The oil has a bland flavour and is without any nauseous taste and smell, such as are associated with cod-liver oil. The strength of the products is controlled by animal feeding tests and also, in the case of vitamin A, by the antimony trichloride test of Carr and Price. The standards adopted are based on that given in the tenth edition of the "United States Pharmacopæia" for vitamin A, which is, that 20 mgm. of cod-liver oil should contain one 'unit,' that is, produce growth in a rat, kept on a diet deficient in vitamins A and D until growth has ceased, at the rate of 2-4 gm. a week for five weeks. The standard adopted for the normal concentrate on this basis is 20 mgm., and for the special concentrate 0.4 mgm.: thus 'Essogen' has ten times the potency required by the United States Pharmacopæia for a cod-liver oil, and 'Advita' fifty times this potency. The dose of 'Essogen' recommended is half to one teaspoonful twice a day, and of the capsules, one per diem. 'Essogen' is put up in 4, 16, and 80 oz. bottles, whilst the capsules are put up in tubes of 24.

Publicity which has recently been given to the establishment of a National Fund for Scientific Research in Belgium, and to arrangements in connexion with the Exhibition of Industry and Science to be held at Liège in 1930, has resulted in some little confusion between these two distinct undertakings. By the courtesy of M. Paul Pelseneer, the permanent secretary of the Royal Academy of Belgium, we are able to record the exact circumstances leading to the foundation of the Fund. Speaking at Seraing on Oct. 1, 1927, on the occasion of the one hundred and tenth anniversary of the establishment of the Cockerill works, H.M. the King of the Belgians referred to the important part played by 'pure' science in laying the

foundations of technical success and industrial prosperity, and deplored the penurious provision which existed in Belgium for the prosecution of study and investigation in that domain. The position was critical, and he looked to private initiative to move, and to sustain effort, in remedying the situation King Albert spoke in no uncertain terms of the serious consequences of neglect in this direction. "Le public," he declared, "ne comprend pas assez chez nous que la science pure est la condition indispensable de la science appliquée, et que le sort des nations qui négligent la science et le savant est marqué pour la décadence... Je demande à tous ceux qui forment l'élite industrielle à penser souvent à nos Universités, à nos écoles spéciales, à nos laboratories."

His Majesty's call to his subjects has not gone unheeded A gathering organised by the "Fondations Hoover pour le développement des Universités libres de Bruxelles et de Louvain," was held at the Palais des Académies, Brussels, on Nov. 27, at which the King, the Diplomatic Corps, the Ministers, and influential representatives of industry, finance, politics, and science were present. A number of delegates from the professoriate of the "Universités libres" and the "Universités de l'État" (Ghent and Liège) presented reports disclosing the difficulties, caused by the paucity of financial resources, which beset them in their scientific work. The King again declared that science, poor herself but the creator of riches, must receive assistance, or the country and her industries would be in jeopardy; that scientific men must be accorded such security and independence as would permit their entire devotion to the service of pure science He then announced the creation of a "Fonds national de la recherche scientifique," foi which a special committee would be constituted, and warmly appealed for support from industrial and financial quarters British scientific workers, to whom their Belgian colleagues' difficulties are not unfamiliar, will cordially wish the new fund all success.

THE Geological Survey of Denmark will celebrate its fortieth anniversary in June next year by a series of excursions and meetings to which foreign geologists are to be invited. Before the meeting to be held in -Copenhagen, two simultaneous four-day excursions will be arranged (June 21-24): to Bornholm, which forms part of the Baltic Shield and is of great petrological, stratigraphical, and tectonic interest; or, alternatively, to Moen and South Sixlland, where remarkable dislocations in the Senoman white chalk can be compared with the undisturbed formations. The meeting itself (June 25-28) will be devoted to lectures and discussions on the general geology of Denmark and to visits to the celebrated museums of After the meeting an eleven-day Copenhagen. excursion (June 29-July 9) will enable visiting geologists to study a wide range of glacial phenomena in north-west Sjælland, Fyn, Langeland, and Jylland. Further particulars relating to the detailed programme, accommodation, and charges will be provided in a later circular. Application for this

may be made to the Secretary of the International Meeting of Geologists, Danmarks Geologiske Undersøgelse, Gammelmønt 14, København K.

The Photographic Materials Preservation Cominittee, which was appointed by the Royal Photographic Society at the request of the Historical Section of the Committee of Imperial Defence of the Australian Commonwealth, has presented its report. The report states that "the production of records by photography has been in existence for so short a period that the Committee is not able to make any recommendations of which it can be said that their application will ensure permanence for all time. All that could be done was to select such processes and methods of treatment as were likely to give the most durable results" It is recommended that negatives and positives on glass be refixed, washed, hardened in chrome alum solution, washed, dried, and varnished with a lac varnish. Negatives and positives on celluloid should be similarly treated, but there is no suitable cold varnish for them. If invaluable, they should be copied on to glass, as both celluloid and cellulose acetate are unstable. Bromide prints should be sulphur toned Finished prints should be refixed, washed, sulphur toned, washed, hardened in chrome alum solution, washed, and dried, and mounted (if desired) by the 'dry' process on boards of the best quality. Mounted finished prints that are invaluable should be copied and the new prints treated as above All prints should be thoroughly dried and varnished by immersion in a solution of gum dammar in benzene. The storage of prints is dealt with, formulæ for the various solutions are given, and also the usual tests in solution for silver and thiosulphates. The carbon and platinum processes of printing are not referred to. It is surprising that printing in platinum, which gives such ideally simple and permanent results, has not been recommended, particularly when new prints have to be made for preservation.

THE region around the headstreams of the Indigirka and the Kolima is one of the least known regions in eastern Siberia. An expedition sent by the Russian Geological Society under S Obruchev penetrated this district in 1926, working east from Yakutsk on the Lena to Moma and Omekonsk on the Indigirka. Between lat. 65° and 66° N. the Indigurka was found to cross, in narrow valleys, a lofty range of snow-clad mountains rising to about ten thousand feet. This range is reputed to be continued eastwards to the Kolima and between the Kolima and the Omolon, and to be about 600 miles long and 180 miles wide. Its further exploration is promised in the near future. The range has been named the Cherski range, after a Russian geologist who lost his life in the Kolima region in 1892. An account of the new range by the discoverer and some photographs of it appear in the Geographical Journal for November. The northwestern end of this range is evidently the Taskhavakhtakh range, but it crosses the Indigirka in a region that was formerly considered to be a low-lying plain. Existing maps of this part of Siberia, however, are far from accurate, and it is difficult to fit the

new features on to the map until more data are available. The Cherski range appears to be built of folded Triassic strata and is roughly parallel with the great folded and faulted arc of the Verkoyansk and Kolimsk ranges.

The elimination of 'atmospherics' which sometimes seriously interfere with trans-Atlantic telephony is a problem to which the Post Office engineers have devoted a great deal of attention. Some of the partial solutions obtained are described in a paper read on Nov. 7 by Colonel A. G Lee to the radio section of the Institution of Electrical Engineers Numerous valuable experimental data have been obtained recently by Watson Watt and others. Generalising from these, the author concludes that an atmospheric is either of an aperiodic or quasi-periodic form It has a peak voltage of about 01 volt per metre and has a duration of the order of 0 003 sec. Sometimes, however, atmospherics are observed which have a fine ripple structure superposed upon the main wave form. The order of strength of an atmospheric is very considerably higher than that of any ordinary commercial radio signal Measurements of these disturbances in Scotland show that they are much smaller there than in the south of England. The noise ratio at Thurso, for example, is only about one-eighth of the ratio farther south. When considerable amplification is being used in radio telephony, owing to bad atmospherics, and electrically charged rain is falling, a loud hissing sound is heard on antenna systems. This is sometimes sufficiently strong to put the service out of action. A receiver should be designed to admit only just sufficient of the signal and its modulation products to ensure intelligibility. This is the best defence against atmospherics. Seeing that these disturbances may come to the receiving station from any point of the compass. it is a great help to employ a directive system of reception as this will be insensitive to atmospherics coming from other directions. This seems to be the only means of defence left which can be improved.

DESPITE the great increase in motor traffic in the streets of Paris and the danger of increased air pollution by dust or gases, the results of the analyses made periodically on the air of Paris at the Laboratory of Hygiene are satisfactory. The percentage of carbonic acid gas averages 30 to 45 parts in 100,000, while carbon monoxide is found only in confined spaces and in percentages varying from 5 to 6 parts per 100,000. M. Kohn-Avrest, reporting on this subject at a recent meeting of the Parıs Academy of Sciences, intends supplementing the ordinary analyses by investigations to determine what he terms the 'smoke vault.' Experiments in this direction have already been made in the gardens of the Champ de Mars and at various levels of the Eiffel Tower. Contrary to what might be expected, the air in these neighbourhoods of Paris may be regarded as very pure, being just as pure in the lower regions as in the upper. On the other hand, vitiation of the atmosphere would seem to increase with the level, either by the

presence of small quantities of carbon monoxide in the upper layers of the air, or by the appreciable increase of carbon dioxide. From these results it may be surmised that the air in the highest regions of the city can scarcely be purer than it is in the lower parts, and that there is a perceptible 'smoke vault' at slightly below 1000 feet. For this reason M Kohn-Avrest is in favour of increasing squares and open places and keeping buildings at a reasonable height.

MR E. F. STEVENS, librarian of the Pratt Institute Free Library, Brooklyn, New York, has favoured us with a copy of a useful annotated list of "Technical Books of 1925" compiled by Mr Donald Hendry, head of the applied science reference department of the library This additional guide to selected scientific and technical books supplements the sources of information referred to by Sır Rıchard Gregory ın the paper on "Standards of Book Selection in Science and Technology" published in Nature of Oct 8. Mr. Stevens informs us that an annual list of technical books has been issued by the applied science reference department of the Pratt Institute Free Library for eighteen years. The annotations are made with great care, and the books are designated by symbols as to their character and scope. The list is distributed free upon request to libraries in many parts of the world; and although it is limited to about one hundred books and cannot therefore be a complete guide for comprehensive libraries in science and technology, it should be of decided value to libraries in general.

"THE Industrial Transition in Japan" is the title of a pamphlet by Mr. M. Holland, published jointly by the National Research Council of the United States and the Japan Society. Japan is to-day distinguished by the liberal official support given to scientific research, and the generous subsidy provided by the government for national research institutes in every branch of industry. There is, on the other hand, little interest in research on the part of industrial organisations, and few private research laboratories in industry exist. Mr. Holland believes that the stimulus to research is hindered by the large number of research workers who have received their scientific training in Germany, Britain, and France, and their consequent dependence on foreign methods, technique, and instruments, and even their preference to publish their results in languages and journals foreign to Japan. In spite of these drawbacks, modern scientific methods have had striking results during the half century that they have been practised in Japan. The booklet contains an interesting outline of artificial pearl culture, and some other aspects of fisheries technology.

The wild life of Spitsbergen has suffered much during the last hundred years from trappers, hunters, and sportsmen. Reindeer, foxes, and walrus, which were once numerous, are now rarely seen in the more accessible parts. One of Norway's first concerns on taking over the sovereignty of Spitsbergen has been to protect the wild life from further destruction. Petermanns Mitteilungen, 1927, Heft 9/10, contains a

summary of the measures that have been proposed. Reindeer are entirely protected until 1934. After that date it is hoped that the stock will have increased enough to allow hunters to take 250 head a year. The Arctic fox, which is the staple of the Norwegian trappers, is not to be taken between April and October, when they are valueless for fur. There seems to be no means of protecting the polar bear, since it is really a sea mammal, and is generally shot on the ice on the high seas. The walrus are protected for ten years No measures are to be taken with regard to other seals and whales. A close season is proposed for the shooting of geese, from July 15 to Aug. 15, and for the collection of the eggs and down of eider ducks. It is further proposed to set apart as reserves for game two national parks, in which all hunting is to be prohibited. The largest is to be in the north-west. and to include about five thousand square miles north of Ice Fjord and west of Dickson and Wijde Bays. The second is to be the small Bear Island, with an area of about seventy square miles.

A serious difficulty in connexion with electric ploughing is the dragging over the ground of the flexible electric cable connecting the tractor plough to the dynamo. A novel method has recently been tried experimentally in Italy of getting over this difficulty. A balloon is used to suspend the connecting cable in the air. An insulated aluminium cable was used. The diameter of the balloon was 17 feet, and its net lifting power was 110 lb. The tractor travelled at a speed of 21 miles per hour and ploughed to a depth of from 12 to 18 inches. The height of the balloon depends on the position of the tractor. As a precaution a steel safety cable is attached to the balloon. This is a novel development of the ancient art of ploughing. In a paper read to the Institution of Electrical Engineers by Mr. Borlase Matthews on Dec. 1, he pointed out that to solve the present farming crisis, agriculture will have to be industrialised by the aid of electric power. He described his experiences of electric ploughs. more than two hundred of which are now in use abroad. Some of the ploughs he described are only suitable for large areas and co-operative or contractor ownership, as they plough from 12 to 30 acres per day. He also describes smaller ploughs suitable for individual small farmers and market A very interesting development in electric ploughing is the action of the electricity supply undertakings who are distributing current in the agricultural area some 30 miles round Paris. They have formed a separate company and a number of operating centres Any farmer in this area can have the use of electric ploughs at the lowest commercial rates. Work can be carried on at night, and once the ploughing season starts there are no stops for Sundays or holidays. An electric plough can make a very deep furrow and can be usefully operated for 200 days in the year.

The sum of £100 is being offered by the Royal Society for the Protection of Birds for an invention of a portable apparatus for the detection of small

quantities of carbon monoxide in mines, to supersede the use of canaries and small wild birds now forming part of the equipment of rescue brigades. Full particulars may be obtained from the Secretary of the Society, 82 Victoria Street, S.W 1. All competing essays should be received by Mar. 31 next.

It is announced in Science that the John Fritz gold medal for 1928 has been awarded to General John J. Carty, of New York, for achievement in telephone engineering. This medal is awarded annually by a board representing the American Societies of Civil, Mining, and Metallurgical, Mechanical, and Electrical Engineers, for notable scientific or industrial achievement, without restriction on account of nationality or sex. This is the twenty-fourth award which has been made. The presentation of the medal will take place in February next in connexion with the annual meeting in New York of the American Institute of Electrical Engineers.

It is announced in a recent Daily Science News Bulletin (No 346 D), issued by Science Service, Washington, that Drs. Leonard and Feirer, of the Johns Hopkins School of Hygiene, have succeeded in utilising hexviresorcinol as a general antiseptic. This substance has been used as an internal antiseptic, but apparently a proper solvent for it was not known, so that it could not be used as a disinfectant solution. It is now stated that an aqueous solution of glycerin (strength not stated) accomplishes this, and that the solution is very potent in killing bacteria, while having little deleterious effect upon the tissues of the body.

WE have received the annual report of Livingstone College, Leyton, for the year 1926–27. The past year has seen the largest entry of students since the College started, and the financial position has therefore improved, though an accumulated deficit of £883 still exists. Donations and subscriptions are needed to help the work of the College, which is to give missionaries instruction in the preservation of health and treatment of disease.

A REPORT by Dr. H. M. Ayres to the Monmouthshire County Council appears in the October issue of *The Fight against Disease*, the journal of the Research Defence Society, on the vaccinal condition of the first 1230 cases of smallpox which occurred in that county between February and July 1927. Not a single case of the disease occurred in a child who had been successfully vaccinated before the epidemic, while among the unvaccinated school children of less than 15 years, there were not less than 355 cases.

Prof Archibald Liversidge, emeritus professor of chemistry in the University of Sydney, who died on Sept. 26 last, leaving estate of the value of £46,000, bequeathed to the University of Sydney two sums of money, £2000 and £500, towards a scholarship and for the advancement of science in Sydney respectively. Other bequests include £1000 and £500 to Christ's College, Cambridge, towards a scholarship and a research lectureship in chemistry respectively; £1000 to the Royal School of Mines, towards a scholarship; £500 each to the Royal

Society of New South Wales and to the Australasian Association, and also to the Chemical Society of London, towards research lectureships in chemistry, as well as a further £100 and his unpublished papers on scientific and chemical matters.—Another recent benefaction, which appears in the will of Mrs. Marryat, sister and heiress of the late Sir James Caird, is a bequest of £200,000 for the foundation of travelling scholarships in engineering, electricity, aeronautics, and music, to be eligible to natives of Scotland only, to be known as 'Sir James Caird's Travelling Scholarships.'

THE Juvenile Christmas Lectures at the Royal Institution will be delivered by Prof. E. N. da C. Andrade on "Engines," commencing on Thursday, Dec 29. The general courses of lectures before Easter will begin on Tuesday, Jan. 17, at 5.15, when Mr. P R. Coursey will deliver the first of two lectures on the development of dielectrics for electrical condensers. On succeeding Tuesday afternoons there will be three lectures by Dr. A. P. Newton on (1) the Mercantile Empire, 1606-1783; (2) the settlement of the Dominions, 1783-1870; (3) the Dependent Empire and the British Commonwealth of Nations, 1870-1926; and six lectures by Prof. Julian S. Huxley on the behaviour of animals On Thursday afternoons at the same hour there will be three lectures by Sir William Bragg on Faraday's notebooks; two by Dr F. Ll. Griffiths on Nubia in antiquity and in the Middle Ages; two by Dr. J. J. Fox on optics and chemistry; and two by Group Capt. M. Flack on the physiological aspects of flying. Sir Ernest Rutherford will deliver four lectures on the transformation of matter on Saturday afternoons at three o'clock. The Friday evening meetings will commence on Jan. 20, when the discourse will be delivered by Sir William Bragg on photo-electricity. Succeeding discourses will probably be given by Miss D. A. E. Garrod, Prof. E. C. C. Baly, Prof. B. Melvill Jones, Rev. E. M. Walker, Sir Farquhar Buzzard, Prof. E. A. Milne, Sir Ernest Rutherford, and others.

Under the energetic leadership of Prof. H. Arctowski, formerly working in the United States, the Institute of Geophysics and Meteorology of the University of Lwow, Poland, has become an active centre of theoretical studies in meteorology. The second volume of Communications, just issued, contains twelve papers by Prof. Arctowski and his collaborators. They are written in Polish, but with summaries in French. The subjects dealt with include the variations of temperature in North America, Japan, China, and Indo-China during 1910–1919; the large-scale transport of mass in the atmosphere; perturbations of atmospheric transparency; and the daily variation of the barometric pressure at Batavia and Manila.

A FULL and useful catalogue of books relating to the East has reached us from the Librairie d'Amérique et d'Orient Adrien-Maisonneuve, 5 Rue de Tournon, Paris (VI°). The works offered for sale are carefully classified under the countries with which they deal. The prices asked are given in French francs.

A NEW part of the well-known "Catalogue of Science and Technology," No. III., of Messrs. H Sotheran and Co, 140 Strand, W.C.2, has just been issued. Its designation is No. 806, Part VIII., including XII., and is devoted to works on mining and metallurgy. As usual with this publication, it is a mine of bibliographical information and should certainly be seen by those interested in the subjects dealt with.

WE have received from Messrs C Baker, 244 High Holborn, W C 1, their classified list (No. 91) of second-hand scientific instruments. Microscopes and microscopic apparatus, particularly objectives and eyepieces, occupy 20 pages of the list and offer a considerable range of first-rate instruments and accessories. Astronomical and other telescopes and field-glasses, spectroscopes, theodolites, and other surveying and drawing instruments, meteorological and ophthalmic instruments, and sundry electrical and other apparatus, are also catalogued. A supplementary list contains the large collection of scientific and photographic apparatus and engineering equipment, the property of the late Mr Edward Sanger Shepherd, which Messrs. Baker have for disposal.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A patho-

logist at the Infants' Hospital, Westminster-The Secretary, Infants' Hospital, Vincent Square, Westminster, S.W.1 (Dec 31). A lecturer in chemistry in the University of Durham (Durham Division)—The Head of the Department of Science, South Road, Durham (Jan. 2). A research assistant in the testing department of the British Cotton Industry Research Association—The Secretary, British Cotton Industry Research Association, Shirley Institute, Didsbury, Manchester (Jan 4). A part-time principal of the L.C.C Clapham School of Art, 6 Edgeley Road, Clapham, SW.4—The Education Officer (Tla), The County Hall, Westminster Bridge, S.E 1 (Jan. 7). A principal of the Technological Institute, Cawipore —The Secretary to the High Commissioner for India, General Department, 42 Grosvenor Gardens, SW.1 (Jan. 15) A professor of chemical engineering at University College—The Academic Registrar, University of London, South Kensington, S W 7 (Jan 23). Two junior assistants under the Linen Industry Research. Association, one with qualifications in physical chemistry and the other in engineering and with some knowledge of chemistry and physics—The Secretary, Linen Industry Research Association, Research Institute, Lambeg, Co. Antrim. A junior assistant chemist for a Government laboratory—The Commandant, Experimental Station, Porton, Wilts.

#### Our Astronomical Column.

Skjellerup's Comet.—Another observation of this comet was obtained by Mr. Maristany at La Plata on Dec. 6d 0h 36m U.T. , R A. 16h 27m; S. Decl 50° 0′; magnitude 2. The object was only  $2\frac{1}{2}$ ° above the horizon.

The following elements were calculated by Mr H. E. Wood (Union Observatory, Johannesburg) and have been telegraphed from the I.A.U.

T 1927 Dec. 1·192 U.T.  

$$\begin{array}{cccc}
\omega & 323^{\circ} & 29'\\
\Omega & 79 & 20\\
i & 72 & 10
\end{array}$$
 1927·0  
 $\begin{array}{cccc}
i & 72 & 10
\end{array}$ 

Ephemens for 0h:

	R.A		Decl		log _	
Dec. 18.	18h 11m	20s	5° 2′	$\mathbf{s}$	9.47	
22.	18 39	44	14 8	$\mathbf{N}$	9.5223	
26.	19 0	58	27 57	N	9 5980	
30.	19 22	51	36.52	N	9.6799	

The comet should become visible in England in the west after sunset about Dec. 20. Its altitude will rapidly increase, but its distance both from sun and earth will increase fairly rapidly, so that it is unlikely to be conspicuous for long.

The values of  $\Omega$ , i, q, are fairly near those of De Vico's comet, but  $\omega$  is 50° smaller, which is too great a difference for identity to be possible.

The Rotation of the Galaxy.—Dr. Oort returns to this question in Bull. Astron. Instit. Netherlands, No. 133. He introduces some faint distant Cepheids to add weight to his determination. They give  $320^{\circ}\pm7^{\circ}$  for the longitude of the centre, agreeing well with the value  $324^{\circ}$  obtained from eight other groups of stars. He considers that his results give an indirect confirmation to the validity of Shapley's parallaxes of distant Cepheids.

Dr. Oort notes that it is possible to explain the motions with a smaller central condensation of mass

than that given in the previous paper. He now gives the density in the inner ellipsoid (the axial ratios of which are 10 to 1) as 0.66 of the sun's mass per cubic parsec, while in the shell outside this it falls to 0.30 of the sun's mass. These values involve the assumption either that there are many stars too faint to see or that there is a large proportion of non-stellar material in the galaxy.

Occultations — Union Observatory Circular No. 72 contains a careful discussion by Dr. Innes of 90 occultations of stars by the moon observed at Johannesburg in 1926 In the mean the correction to Brown's longitude of the moon is +7''3. The error has only varied very slightly since the introduction of Brown's tables in 1923 Dr. Innes gives the error as wholly one of time (due to variable rotation of the earth), it seems inadvisable to put the whole of it down to this source. Prof. Brown now admits that the secular acceleration of the moon is some 4" greater than the term used in his tables, this involves consequential changes in the longitude at epoch and mean motion; also there is a small correction to his longitude of perigee. Only the residue after making these corrections should be ascubed to variable rotation of the earth.

The circular also contains some observations of phenomena of Jupiter's satellites, and the deduction of time-errors from them. The mean error for the last four years is  $-43^{\rm s}$  7 for satellite I, and  $-45^{\rm s}$ ·8 for II.; these errors have increased greatly for both satellites since 1909, but seem now to have reached a maximum.

There are also some interesting observations of mutual eclipses by the shadows of other satellites, and comparison of these with the predictions in the B A.A. Handbook for 1926. On June 29, 1926, an unusually dark transit of IV. was observed, and on Aug 15, 1926, the date of opposition, I was seen on the disc partially covering its shadow.

## Research Items.

STRING FIGURES IN OCEANIA.—Mr J. Hornell has published as Bulletin 39 of the Bernice P. Bishop Museum of Honolulu, a record of string figures collected in Figure and in the Marquesas, the Society Islands, and Samoa and Tonga. Although these figures had not hitherto been recorded in Samoa, it is probable that further research would produce numerous examples Tonga proved a rich field for study, but the largest number, 58, was obtained from Fiji. Most Fijian figures are named after the object they are supposed to represent, the owl, the caterpillar, the butterfly, and so on; others represent trees or the leaves of the pandanus. In a few the Fijians see a resemblance to the sun and his rays, and one is named "The Star." The figures showed no mythological significance, but this may have been lost under missionary influence A large number were originally worked to the accompaniment of a chant, some of which must have been of great antiquity, as the significance of the words has been lost. The geographical distribution of the figures suggests certain ethnological affinities Of these the most striking is the predominance of Melanesian influence in Fiji. Of 30 figures and series of figures, 12 occur in New Caledonia, Torres Straits, Fly River, New Gunea, Loyalty Islands, and D'Entrecasteaux Next in importance is relationship with Tonga, 7 figures being in common. Six of the Fijian games are Polynesian, being found in the Marquesas and Society Islands. Of these one is the most widely spread of any string game in Oceania The Toi games are wholly Polynesian if Fiji be excluded. The Tongan

Marine Biology at Millport.—The annual report for 1926-27 of the Scottish Marine Biological Association shows that a large amount of work has been done both by the staff and by the visitors. The valuable researches on plankton undertaken by the hydrographer, Mr. A. P. Orı, and the assistant naturalist, Miss S. M. Marshall, are still progressing. Following the work on Loch Striven, begun in 1926, now complete and published in the Journal of the Marine Biological Association, various experiments were made on the biology of diatoms, and these are still in progress. It was found that direct sunlight was injurious, specimens from five fathoms and more appearing much healthier than those from the surface, and diatom cultures grow best in the shade. A comparison of the amount of sunlight and diatom maxima extending over a period of three years shows that, unlike the results from Plymouth and Port Erin, the latest diatom maximum actually corresponded with the year which had most early sunshine. It is suggested that a measurement of the total amount of incident light, and not of sunshine alone, would be a more trustworthy guide. Mr. R. Macdonald, Carnegie Research Student, in continuing his work on the Euphausudæ, has completed the life-history of Thysanassa Raschii which is very abundant in the district. A survey of the sandy bays of Cumbrae by the superintendent, Mr. R. Elmhirst, and Mr. A. C. Stephen, with special reference to the biology of Tellina tenuis, begun only recently, should yield interesting and important results. This molluse is exceedingly common in Kames Bay, the numbers sometimes reaching more than seven thousand per square metre in one station.

BIOLOGICAL INVESTIGATIONS IN THE BLACK SEA.— The Sevastopol Biological Station of the Russian Academy of Sciences (according to the *Information Bulletin* of the Academy, No. 20, 1927) carried out

during the last summer a series of investigations in the Black Sea. A study of distribution of animal life was undertaken during two expeditions, one along the Crimean shores, while another covered a large area m the eastern portion of the sea It was found that the fauna near the shores of the Caucasus and Anatolia is considerably poorer than that near the Crimean shores. The lower limit of benthos has been found not to drop below 140-160 metres, while in some parts it is still nearer to the surface. The lower limit of plankton proved to be also not deeper than 150-170 metres, and in some places in the central part of the sea it has been found only 90-100 metres deep; in all cases the vertical distribution of plankton proved to be directly connected with the distribution of oxygen and of hydrogen sulphide in the water. Hydro-chemical work included also determinations of carbon dioxide in the water, for the first time in the Black Sea, and it has been found that the quantity increases with the depth, and reaches a very high absolute figure

THE HELIA BIP.IRTIT.1 OF AUSTRALIA.—The conspicuous Helix bipartita of Pfeiffer, hailing from north-eastern Australia and its neighbouring islands, and now placed in the genus Thersites, section Hadra, with all its innumerable varieties of form and size, has long been well known to collectors, who have been content to refer them to one, or at most four species. Now, however, a large collection has been presented to the United States National Museum, and Mr W. B Marshall, having arranged them in geographical sequence, considers that many characteristics are thereby revealed, showing that specialisation has taken place along certain definite lines and that the recognition of additional species and sub-species is necessary (Proc. U.S Nat. Mus., vol 72, art. 15). His list now contains twenty-seven names, including T. darwini, which he has not seen Four of these are given as new species, and the bulk are new 'sub-species' which may or may not prove valid. Since the author has adopted the method of late employed by certain zoological writers, more especially ornithologists, of stringing the sub-specific name on to that of the species, his nomenclature is for the most part quadrinominal instead of binominal. His paper, however, will have to be seriously reckoned with by anyone taking up the group.

JAPANESE JELLY-FISHES.—The Anthomedusæ of Japan are many and varied and a number of beautiful and interesting forms are described by Dr Tohru Uchida ("Studies on Japanese Hydromedusæ. I. Anthomedusæ." Journal of the Faculty of Science. Imperial University of Tokyo. Section 4. Zoology, vol. 1, Part 3, 1927). Not only is the morphology of all forms carefully worked out and a satisfactory classification arrived at, but also the life-histories are studied whenever possible, and very important additions are made to our knowledge of the metamorphoses in this group. The author bases his systematic work mainly on the structure of the canals, tentacles, manubrium, and gonads, regarding the oral tentacles and ocelli as of only secondary significance. An account of the early development of  $\bar{S}pirocodon$ saltatrix is given, showing that spawning always takes place after sunset in natural conditions, but if brought into a dark room the medusa will lay eggs in half an hour to an hour, so that these are easily obtained for study. The hydroid is not known, but the development from the very young medusa is described, showing a wonderful series of changes beginning from a simple Sarsia-like form and passing through phases

corresponding with the Tiaridæ and Nemopsis until the final adult Spirocodon is reached. The principal changes are the appearance of numerous side branches from the radial canals, four arborescent canals from each inter-radius, the multiplication of the marginal tentacles, complication of the manubrium by frilling of the lips, development of the gonads, which form spirals in the radial canals, and the formation of a central cone of jelly. Good reasons are given for relegating Spirocodon saltatrix to the Anthomedusæ together with Polyorchis and Scrippsia instead of to the Leptomedusæ where they were formerly placed on account of the position of the gonads

Tertiary Mollusca of Japan Prof. M. Yokoyama contributes (Jour. Fac Sci Imp. Univ Tokyo, Sect 2, vol 2) three more papers on the Tertiary Mollusca of Japan From the province of Kaga, about the middle of the northern side of the principal island, a series of some 120 species of mollusca was obtained referable to the Musashino, or Phocene, and the more important species are described and figured As before, the author finds that the sea of central Japan was somewhat cooler then than at present. From Western Hizen, in the neighbourhood of Nagasaki, a few fossils, including fourteen mollusca, mostly badly preserved and of Phocene age, have been procured and form the subject of the second paper. The third paper describes those mollusca found in the Chikbets (Phocene) and Haboro (Miocene) beds in the coalfields of Haboro, Province of Teshio, at the northern end of the Island of Yezo. Some thirty-three species are described and figured.

LIGHT REFLECTION FROM LEAVES.—Prof. Chas. A. Shull, of Chicago, gave some interesting details regarding the reflecting power of leaves at a recent meeting of the National Academy of Sciences held at Washington. A report of the paper has been issued by Science Service, of Washington. Prof. Shull finds that different leaves reflect different proportions of the incident light, and the same leaf reflects light of different colours in different percentages. Thus the upper surface of a silver poplar leaf reflects 7.5 per cent. of one of the violet hues, and 20 per cent. of the light in the green-yellow part of the spectrum. The upper and lower surfaces of the same leaf have different reflecting powers The silver poplar leaf, which is dark green above but shining white beneath, reflects 85 per cent. of the deepest red rays from its upper surface and 50 per cent. of the same rays from its under surface. Autumn coloration of leaves also influences their reflecting power. Red leaves of woodbine reflect nearly twice as much red light as they do of violet; but their total reflection is far less than that of bright yellow birch leaves, which reflect more than 40 per cent. of the incident light, as against 13 per cent. for woodbine.

Timber Seasoning.—Timber in various forms is in such universal use that the importance of its proper seasoning before manufacture and utilisation is beyond dispute. With the imcreasing demands made upon the world's timber resources and the diminishing supplies, any factor which will assist in prolonging the durability of wood, and therefore its longevity when manufactured, will lessen in some degree the calls upon the forests. Seasoning is well understood by many persons in the timber trade. The practical disappearance of all stores of seasoned timber in Great Britain during the progress of the War has, however, disclosed the fact that a considerable section of those interested in timber and its seasoning are not so knowledgable. The new Forest

Products Research Laboratory at Princes Risborough has recently issued a report by Major F M Oliphant on "The Air Seasoning and Conditioning of Timber" (Special Report No. 1). The report does not pretend to deal with new facts. Its author has had two objects in view: first, to discuss the fundamental factors governing the process of drying timber, and secondly, to illustrate methods by which such factors can be utilised to season it to the best advantage. The structure of wood and its moisture contents, weather aspects, especially as regards moisture, are first dealt with, followed by sections treating of defects caused by air-seasoning, and various methods of piling timber in stacks for air-seasoning, the report is illustrated, the photographs of stacking methods being particularly useful

INHERITANCE IN MORNING GLORIES —In a genetical investigation of Pharbitis purpurea, which is closely related to the Japanese morning glory, P Nil, Mr Yoshitaka Imai (Jour Coll Agric, Imp Univ Tokyo, vol 9, No. 3) records certain interesting genetic differences from the latter species The heterozygous condition of flower colour is intermediate in P. pur-purea but dominant in P. Nil There is an intensifying factor for red colour, which shows its effect in corolla and stem and also in changing the seed from tan to black, absence of the red factor producing white flower and green stem. Another factor causes extension of colour in the corolla, and here again the heterozygous condition is intermediate factor may also be present, but its effect can only be detected in the presence of the extension factor. feathered double type of flower occurs, similar to that of the other species, but it produces good seeds, whereas the double  $P.\ Nil$  is sterile. It behaves as a simple dominant in crosses, and there appears to be a low degree of linkage between doubleness and flower colour. More recent results by Prof K. Mıyake and Dr. Imai (Jour. of Genetics, vol 19, No. 1) show that in P Nil the common petaloid double is recessive to single flower. Many forms of doubling are found to exist in this species and they have been analysed genetically, so that the breeders' difficulties in perpetuating their stocks can now be overcome four main types of doubling, some of which can be combined by crossing In petaloid forms the pistil is fertile and the petaloidy commonly occurs on the anthers, but may refer to the filaments In the 'Shishi' type the corolla tube is broken up into narrow lobes which take various forms, and the sex organs are more or less deformed. The 'Botan' type has no stamens or pistil, and the corolla tube contains additional flower buds All these and other monstrous types, which are much admired by the fanciers, are shown to be determined by a series of genetic factors. The original doubles were introduced from China over a thousand years ago.

Surveying from Air Photographs —In 1926 the Ordnance Survey experimented in air surveys in an area of 20 square miles near Arundel. The result was encouraging both as regards the speed with which the work was done and the standard of accuracy achieved Moreover, the total cost was found to be reasonable, though the cost of air photography is high. On the other hand, the expense of aerial survey would not increase on difficult ground where the expenses of the usual form of survey would rapidly mount. In such areas, therefore, the air method would be the most economical. The detailed procedure of the Arundel Survey, with an account of the instrumental output, is given in a paper entitled "Simple Methods of Surveying from Air Photographs," by Lieut. M. Hotine

(Professional Papers of the Air Survey Committee, No. 3. London · H.M Stationery Office) The paper contains a chapter on the making of controlled mosaics. There is also a specimen 6-inch drawing on transparent paper with the usual Ordnance Survey on one side and the aerial survey on the other.

THE ENERGY OF CYCLONES.—The problem handled by V. H. Ryd, in Meteorological Problems (2), "The energy of the winds" (Publikationer fra det Danske Meteorologiske Institut, Meddelelser Nr 7, pp. v+96, Kjobenhavn, G E. C Gad, 1927), is the fundamental one of the source of the energy developed in cyclones and anticyclones After a careful examination of some simple cases in which the conditions can be worked out and definite conclusions reached, the author considers Margules' theories as stated in Exner's "Dynamische Meteorologie." He concludes that only a small part of the energy of a cyclone is to be found in the horizontal pressure field, and that if this field was expended, the kinetic energy generated would only be a small fraction, say 1/100, of its energy; the pressure field is rather to be looked upon as "the means whereby energy is transported from the atmosphere to the inner part of the depression "Margules' example of the energy available from the juxtaposition of masses of air at different temperatures is criticised on the ground that in Nature, where we have no partition walls, most of the potential energy would be spent in vertical velocities, ending in turbulence and heat; and this conclusion is in agreement with Hesselberg's results. This destructive criticism calls for something constructive, and Ryd produces a theory that the energy of cyclone formation comes from the west-easterly motion of the upper air. Here a locally strong wind will be deflected to the south and will produce a small area of low pressure, the effect of which is by some means transmitted downwards advantages claimed for this theory are that it accounts for the escape of the air that ascends in a cyclone, and for Hesselberg's law that the direction of cyclone motion is that of the cirrus cloud.

Insulating Materials for Telephone Switch-BOARDS —The problems which the designers of telephone switchboards have solved are appreciated by few. In one type of switchboard, there are 31,000 contacts, all insulated from one another, in an area five feet wide and two and a half feet high. electric leakage on the surface and sometimes also through the material of the insulator itself often causes trouble. In damp weather the insulation resistance is often only a small fraction of what it is in dry weather For telephone work, only insulating materials which are little affected by moisture can be used. Hence hard rubber, phenol fibre, and vulcanised fibre are widely used. Hard rubber in particular is an excellent insulator, but when subjected to long continued stresses it yields This yielding is generally known as cold flow,' the hard rubber acting like an exceedingly viscous liquid. Another limitation to the use of hard rubber is its rapid deterioration when exposed to light. These two objections to the use of hard rubber have led to extensive researches to discover a better material. Various kinds of phenol fibre are found to maintain their insulation resistance much more satisfactorily than hard rubber, and these are put on the market under various trade names. Vulcanised fibre is also extensively used. In the October number of the  $Bell\ Laboratories\ Record,\ J\ M.$  Wilson discusses the properties of sheet insulating materials. Many new varieties of these materials are tested in the Bell laboratories, and records are kept of the difference between their properties and those of the existing materials for which they are proposed as substitutes.

THE SPECTRA OF SCANDIUM.—The analysis of the are and spark spectra of scandium is described by H N. Russell and W F Meggers in a paper (No. 558) from the U.S. Bureau of Standards These are of special interest from the fact that they come from the lightest element which possesses the complicated spectra of the type associated with the heavier metals. Some five hundred lines in all have been referred to spectral terms, leaving only a few scattered lines of feeble intensity unclassified. Almost all of the terms have been identified with definite atomic configurations, and it has thus been possible to find the beginnings of a number of series which lead to consistent determinations of the ionisation potentials. From the data obtained in this way, it has been shown that the energy required to ionise the neutral atom is 6 65 electron-volts, whereas from comparative observations of furnace spectra it should be between the values for calcium (6 l volts) and titanium (6.8 volts), whilst equally good agreement is obtained between the second ionisation potential of 128 volts predicted from these spectra, and a value of 125 volts which has been derived from the conditions of appearance of ionised scandium in stars.

THE CATALYTIC SYNTHESIS OF WATER VAPOUR IN CONTACT WITH METALLIC GOLD. The October number of the Journal of the American Chemical Society contains an account by A. F. Benton and J. C. Elgin of an investigation of the union of hydrogen and oxygen in the presence of a reduced gold catalyst between 130° and 150° C. Measurements of the reaction kinetics and the adsorptions of the two gases were made, but no satisfactory mechanism for the reaction could be deduced from the observed results. In spite of the similarities in their chemical properties and adsorption phenomena, gold and silver appear to bring about the catalytic synthesis of water vapour in quite different ways. It was found that the rate of reaction with a gold catalyst is dependent upon the oxygen pressure and the square of the hydrogen pressure, whereas Bone and Wheeler found that it was independent of the oxygen pressure. Benton and Elgin suggest that this apparent discrepancy may be due to the higher temperatures used by Bone and Wheeler.

THE DIELECTRIC CONSTANTS OF BINARY MIXTURES. Two papers on this subject by Kirchma and Williams, and Williams and Allgeier, appeared in the Journal of the American Chemical Society for October. The first paper contains dielectric constant and density measurements for solutions of benzene, toluene, chloroform, ethyl ether, methyl and ethyl acetates, acetone and ethyl and iso amyl alcohols in carbon tetrachloride. The dielectric constants were determined by an electrical resonance method or by a new 'bridge' method. The electric moments of the molecules of the dissolved substance were calculated, and it was found that the moment of the benzene molecule is practically zero. It was also observed that the electric moments of organic molecules tend to increase as the length of the carbon chain increases. This is in accordance with the results of previous workers. The second paper contains similar measurements for benzene solutions of benzoic acid, phenol, iodine, stannic iodide, antimony tri-iodide, and silver perchlorate, and the values obtained for the electric moments are discussed in relation to atomic structure and solubility. The value for iodine is considered in some detail, since if the iodine molecule is symmetrical, its moment should be zero, and attention is directed to the explanation advanced by Lewis, who has shown that a symmetrical molecule such as iodine may become polarised and consequently have an electric moment.

## Dutch Pendulum Observations in the Atlantic, the Pacific, and the Indian Oceans.

AN account of the first part of Dr Vening Meinesz's voyage on board HM. Submaine KXIII from Helder to Honolulu through the Panama Canal was published in NATURE of Dec. 25, 1926. I propose now to give some particulars about the voyages from Honolulu to Surabaya and to the Java Deep.

In my first communication I mentioned that the number of observations between Honolulu was 32;

there were further ·

Manila—Amboma, Nov 20-Nov. 25		6
Amboma—Banda, Nov 25		1
Banda—Bima, Dec 2-Dec 6		8
Bima—Surabaya, Dec 7-Dec 13		1

The number of observations at sea during the whole voyage is 113, 2 of which were made at the surface of the sea: in the Atlantic, the Philippines, the Straits of Manipa (Moluccas), and the Java Sea. Through a misunderstanding I mentioned in my first communication that the observation in the Atlantic was a failure.

Several observations were made on the same day:

<b>2</b>	observations		. 10	times
3	,,		. 4	,,
4	,,		. 2	,,

Double observations at sea were made 5 times, 3 of which sailing east and west (Eotvos-effect) and 2 with the freezing apparatus working and idle.

The number of observations in the harbours was 15, all were double, with free hanging apparatus and with fastened gimbals.

The time signals used were those of Lembang, Java, given by the radio station of Malabar. Between Honolulu and Manila the signals of Saigon were also audible, and after leaving Manila those of Bordeaux.

Because of the high temperature the films were no longer developed on board, but whenever a harbour was reached development took place. In the long run the quality of the films became less satisfactory; but though the records were not so perfect as might have been, they were still efficient.

The crossing from Honolulu to Guam in nineteen days was exceedingly trying, the temperature of the sea-water being 30° or 31° C. Owing to a leakage, the freezing machine lost all its methyl chloride and remained out of action for the rest of the voyage, as no supply could be made in any of the harbours at which the submarine called

From Guam so far as the Straits of Surigao the weather was very rough, but happily the ship was in the rear of the typhoon which had swept over part of

the Philippines just before its arrival.

The crew met a friendly reception at Guam, Yap, and Manila. On the arrival in the Dutch harbours Amboina, Banda, and Bima they were splendidly received by the authorities and by the population. From Banda the ship did not sail straight to Bima, but in order to make observations it went first in a southern direction so far as the Sahul shoal on the shelf of the Australian continent. In this manner the curved double range of islands on the border of the Banda Sea was crossed twice.

Banda Sea was crossed twice.

On Dec. 13 the ship arrived at Surabaya after a voyage of 200 days, 112 of which had been sailing days. The length of the whole track is 20,600 miles. Never before has so long a voyage been performed by an unescorted submarine. The crew arrived in good health notwithstanding the hardships of so long a stay on board the small vessel, which measured but 800 tons and offered very poor accommodation. The ship and the engines, built at the yard 'Feyenoord' at

Rotterdam, were during the whole voyage in the most perfect condition

Vice-Admiral A F. Goossens, Commander of the Fleet and Chief of the Navy Department at Batavia, was present to welcome the crew, and informed Commander van der Kun and Dr Vening Meinesz that H M the Queen had been pleased to make both of them officers in the Order of Oranje-Nassau, whilst many among the officers and the crew received other marks of distinction. The first days at Surabaya

brought a series of festivities.

After having made one more observation in the harbour of Surabaya, Dr. Vening Meinesz was able to go to the mountains for a well-deserved rest. But again and again this rest was interrupted by his giving lectures in the principal towns of Java about his voyage.

On meeting the admiral at Surabaya, Dr. Vening Meinesz had availed himself of the opportunity to request if before his return to Holland H.M. Submarine K XIII could once more be placed at his disposal for the making of pendulum observations in the deep south of Java This request was granted directly; so, on Feb. 3 he again embarked at Surabaya and sailed through the Straits of Bali into the Indian Ocean. The observations were made in four profiles perpendicular to the Java Deep; they are twenty-six in number, and will give a complete record of the gravity in this part of the ocean. The results have not yet been computed

The submarine sailed through the Straits of Sunda to Batavia, where Dr. Vening Memesz disembarked on Feb. 14. He left Java on Mar. 9 on board a mail steamer, and arrived at Amsterdam on April 9. At the meeting of the Amsterdam Academy of Sciences on June 25 he read a paper upon the provisional results of his observations and the conclusions which, with some reservation, may be drawn from them. These conclusions are principally the following:

1. In the Atlantic and the Pacific there are excesses of gravity extending over large areas. As has been explained by Dr. W. Bowie and C. H. Swick, both of the U.S. Coast and Geodetic Survey, these may be caused partially by a depression of the geoid with regard to the spheroid. The final computations will show in how far this circumstance may account for the excesses.

2. It is unlikely that the longitude terms introduced by Helmert and by Heiskanen in the formulæ will agree with the values of gravity obtained in the oceans

3. In the Pacific there exists a remarkable parallelism between the variations of the anomalies and of the sea-depths.

4. The observations made above the four deeps all show a remarkable defect of gravity in the middle of the deep. The excesses on the borders do not make the impression that they may be ascribed to an excess of mass below the deeps, required for isostatic compensation, but give rise to the supposition of tangential pressure in the earth's crust.

5. The observations at the feet of the continental slopes give greater values of the gravity than should be the case according to the current theory.

6. The results obtained in the Banda Sea, especially near the double range of islands, show a large excess at the inside; that gradually changes into a very noticeable defect at the outside, where the tangential pressures which are probable in this part of the archipelago should make an excess probable. The great anomalies are in accordance with the general view that in this part of the world the earth-crust was recently, or is still at present, in a labile condition.

7. In general, the results obtained at sea give the impression of greater regularity than those obtained on land. This agrees with what was expected. The outer layer of water immediately below the observer is homogeneous and the disturbing masses in the solid crust are farther away. Moreover, the deformation caused by erosion is absent

The list of the provisional results of Dr. Vening Memesz's o'vservations in the Atlantic and the Pacific is published in the *Proceedings of the Amsterdam Academy of Sciences*. The complete definite results, together with the isostatic reductions computed by the courtesy of the U.S. Coast and Geodetic Survey.

will be published by the Dutch Geodetic Committee in the course of 1928

Thanks to the skill of Dr. Vening Meinesz, the problem of the determination of gravity at sea is solved By his indefatigable effort and the splendid co-operation of the Royal Dutch Navy, the earth is now surrounded by a chain of gravity observations, which will procure the necessary data for a crucial test of the existing theories about the constitution of the earth's crust. Dr. Vening Meinesz has been appointed professor of geodesy at the University of Utrecht, and is now a member of the Dutch Geodetic Committee.

J. J. A. Muller.

## Forestry in Kenya Colony.

THE Forestry Department in Kenya has been in existence for more than a quarter of a century, the Forestry Ordinance dating from 1911. annual report for the year ended Dec. 31, 1926, it is claimed that the year then dealt with was "a notable one, and in many respects the most successful in the history of the Department " For the first time, it is said, the revenue was in excess of the expenditure. The revenue of £36,938 exceeded the expenditure by £7083 and was 45 per cent larger than that of any previous year. The Acting Conservator rightly remarks that a record exploitation of the forests would not necessarily imply a successful year. It might mean, he adds, as it has in many countries, record forest destruction and diminution of the capital forest wealth. Unfortunately, such destruction is still in force in different parts of the world. But it may be asked, is Kenya herself on sure ground in this respect? It is true the Acting Conservator points out that the record exploitation in Kenya in 1926 was accompanied by record progress in afforesta-tion and re-afforestation. "the area of 3047 acres planted during the year being more than sufficient to replace the forest cut during the year." It is not apparent, however, from the report, on what premises such a statement rests.

One of the most serious features of the present position of the Department and its forests is to be found in the fact that no trustworthy estimate of the quantities of timber in the forests exists; in other words, no enumeration of the growing stock as a whole in the forests under the Department has yet been made. This the report quite rightly states is "the most unsatisfactory aspect of the forestry position."

The exploitation work is carried out by sawmill companies, which are granted timber-felling licences. Twenty-three of these firms worked in the forest reserves during the year, the area subject to such exploitation being approximately 447,518 acres, though it is estimated that not more than 197,700 acres of this area carried marketable timber. "As the rate of cutting," says the report, "varies very greatly with the different licence-holders, the total area under licence is no guide to the rate of exploitation of the Colony's forests. The only sure criterion by which to judge the Colony's forest position is a comparison of the annual cut with a reliable estimate of the total stock of mature timber in the forests. There is at present no such estimate available, nor can one be obtained without a considerable increase of the present Staff of the Department."

The plain meaning of these statements is that the forests are being worked without an adequate knowledge of their contents or what is the annual possibility. It should not prove difficult to settle this important matter, if only roughly, in order to avoid the grave chance of overcutting. It is fairly common knowledge how Brandis, single-handed,

tackled a like proposition in Pegu in Burma in 1856. The Department in Kenya is obviously understaffed. But at least there is a trained officer in charge of each forest district. It can surely not be held that there is any work, however apparently important, not even planting work, which should take precedence over the carrying out of enumeration surveys, however rough, of the growing stock of the forests. For the exploitation work being conducted and the revenue accruing thereby is only justified, in economic forestry, when based on some adequate knowledge of the volume of growing stock per unit of area standing in the forests. Such knowledge, the Acting Conservator states, is non-existent. In its absence, fellings, according to modern forest practice and precept, should be made as sparingly as possible.

The other point in the report is the assertion that the planting work undertaken during the year, amounting to 3047 acres, is more than sufficient to replace the forest cut over during the same period. The volumes obtained from the latter were 1,316,566 cub. ft. of timber and 5,207,403 cub. ft of firewood. An analysis of the planting work shows that 1195 acres were planted as fuel plantations for the supply of firewood to the railway. This area has no reference, therefore, to future timber production. The planting work to replace the timber felling comprised 860 acres of pencil cedar, 276 acres of other indigenous timber species, and 274 exotic timber species, or an area of 1410 acres in all. The balance of 442 acres was mangroves Though admittedly a considerable portion of this planting work is still in the experimental stage, yet considerable success is being attained. Nevertheless, it appears somewhat optimistic, with the known history of the costly failures which have been experienced elsewhere in the past, to claim that this planting work will suffice to replace the forest areas cut during the year.

The report points to the necessity of undertaking research work in connexion with the forests and the need of special research officers. The beginnings of such research work have been initiated by the staff, and some very creditable work has already been achieved. Work of this nature, however, must be carried on with continuity, and the latter is not possible in the absence of the whole-time worker. But the mere enumeration of the growing stock of the Kenya Forests does not fall within the province of 'research.' It might be suggested that the best solution of this research question, as in the long run of the staff and its future prospects, would be the amalgamation of the gazetted forest staffs of the four colonies, Kenya, Uganda, Tanganyika, and Nyasaland, on to one list; following the precedent forced upon India some years after the Forest Service there was maugurated.

In conclusion, it should be said that this report is a most interesting document and beautifully got up by the Government Press, Nairobi. In this latter respect it forms a model which some other Colonial government presses might take as a guide.

# University and Educational Intelligence.

Cambridge.—Mi R. H. Fowler, Trinity College, has been elected Stokes lecturer in mathematics. Sir Michael Sadler has been appointed Rede Lecturer for 1928, and Prof G H Hardy has been appointed Rouse Ball lecturer in mathematics for 1928.

Girton College announces that a scientific research fellowship of the annual value of £300, tenable for three years, is offered for research in mathematical, physical, and natural sciences. Particulars are obtainable from the Secretary of the College. The latest date for the receipt of applications is Feb. 1.

London.—Applications are invited for the Keddey Fletcher-Warr studentships for post-graduate research The studentships are each of the annual value of not less than £200, are tenable normally for three years, and are open to men and women graduates of a British university, or who have passed an examination necessary to qualify for a degree, preference being given to a graduate of the University of London Applications should reach the Academic Registrar, South Kensington, S W 7, not later than Feb 20 next.

OXFORD.—The honorary degree of doctor of science has been conferred upon Mr. Edward Ball Knobel for his distinguished contributions both to astronomical science and to Persian scholarship. Dr Knobel has been president of the Royal Astronomical Society for two periods of office.

Among the financial decrees which have recently been brought before Congregation are those for the provision of senior studentships (£1000), for an assistant in the department of medicine (£150); for the botanical department (£450), and for providing and housing a destructor at the University Museum (£350).

A new botanical schedule for the Preliminary Examination has been published. It is to come into force on Oct. 1, 1929.

WITH the September issue of the Journal of the Imperial College of Tropical Agriculture, a 'Sugar Supplement, has been issued which describes briefly the system of training adopted at the Imperial College of Tropical Agriculture, Trinidad, for students in sugar technology, and also gives an idea of the courses of study available at that College for students in tropical agriculture. Before entering upon the special course of study in sugar technology, which occupies a year, the student must have gamed the diploma awarded by the College to those who qualify by examination after undergoing a three years' course of study; the qualification for entrance to the College being the matriculation certificate of any university within the British Empire or its recognised equivalent. The sugar technology course, which is fully described, includes instruction in genetic research on sugar-cane, sugar-cane breeding, agronomic research in the sugar industry, theoretical and practical instruction in the extraction of sugar from canes, by-products of the sugar industry, the components of sugar-cane juice, chemical research problems in sugar-cane production, organic manures from sugar-cane, insect pests of sugar-cane, mycological and bacteriological problems connected with sugar-cane, questions of hygiene connected with life in the tropics and work in factories, and costings and records connected with the management of sugar-cane estates and factories. In each case an outline is given of the course of instruction, whilst some thirteen illustrations depict various cultural operations and factory features.

### Calendar of Discovery and Invention.

December 18, 1879 —Huggins was a pioneer in the use of photography for the investigation of the physical condition of the stars. In 1864 he discovered that many of the nebulæ give spectra consisting of bright lines. In 1876 he obtained a photograph of the spectrum of Vega, and three years later, in a paper to the Royal Society, read on Dec. 18, 1879, he described the ultra-violet spectra of white stars.

December 19, 1844—Just after his return from England, Liebig, on Dec. 19, 1844, writing to Faraday, said. "What struck me most in England was the perception that only those works which have a practical tendency awake attention and command respect, while the purely scientific works, which possess far greater merit, are almost unknown . . . Here, in the eyes of scientific men, no value, or, at least, but a trifling one, is placed on the practical results. The enrichment of science is alone considered worthy of attention. I do not mean to say that this is better, for both nations the golden medium would certainly be a real good fortune."

December 19, 1898.—It was on this date that Prof. and Mme Curie communicated to the Paris Academy of Sciences a memoir, "Sur une nouvelle substance fortement radio-active contenue dans la pechblende," the substance being named by them 'radium.'

December 20, 1842.—Darwin made many experiments to study the action of earthworms. "One experiment lasted nearly thirty years, for a quantity of broken chalk and sifted coal cinders was spread on Dec. 20, 1842, over distinct parts of a field near Down House, which had existed as pasture for a very long time. At the end of November 1871 a trench was dug across this part of the field and the nodules of chalk were found buried seven inches. A similar change took place in a field covered with flints, where in thirty years the turf was compact without any stones."

December 21, 1736—The patent of Jonathan Hulls for a steamboat was granted on Dec 21, 1736. The following year he published a description of his new invention, but so far no evidence has been found showing that he ever put his ideas into practice.

December 22, 1666.—The Royal Academy of Sciences of Paris was founded by Colbert in 1666, and its installation took place by order of Louis XIV. on Dec. 22, 1666. At first there were only twentyone members, including three anatomists, two chemists, three physicists, three astronomers, and seven geometers. Huygens was included as a foreign associate.

December 22, 1896.—The Davy-Faraday Research Laboratory of the Royal Institution was founded and endowed by Ludwig Mond for furthering original investigations in chemical and physical science, and was opened by King Edward VII. on Dec 22, 1896, Lord Rayleigh and Sir James Dewar being appointed directors without remuneration.

December 24, 1801 — Trevithick was the first to run a locomotive on rails, but his earliest steam vehicle made its trial trip on the roads of Camborne on Christmas Eve, 1801. This vehicle was referred to ma Falmouth newspaper, which said · "A carriage has been constructed, containing a small steam engine, the force of which was found sufficient upon trial to mpel the carriage, containing several persons, against a hill of considerable steepness, at the rate of four miles an hour."

### Societies and Academies.

#### LONDON

Royal Society, Dec 8-R W. James and E M Firth · An X-ray study of the heat motions of the atoms in a rock-salt crystal The ratio of the intensity of reflection of X-rays by rock-salt at the temperature of liquid air, to that at room temperature, has been measured for a number of spectra The temperature factor is of an exponential form, the exponent being proportional to the square of the order of the spectrum. within the errors of experiment. The method of Fourier analysis has been used to calculate the distribution of electrons between the (111) planes of the crystal at different temperatures, and from the broadening of the peaks in the distribution curves the mean amplitudes of the atomic vibrations have been estimated.

I. Waller and R W James. On the temperature tactors of X-ray reflection for sodium and chlorine in the rock-salt crystal The factor for Na is greater than that for Cl, indicating that the Na atoms are the less firmly bound in the crystal lattice, and therefore have a greater mean amplitude of vibration than the From the values of the temperature factors the root-mean-square amplitudes of vibration of Na and Cl are found to be 0 242 A. and 0 217 A respec-tively at 290° abs Waller's theoretical formula for the temperature factor agrees with experiment from 86° abs to about 500° abs if allowance is made for

the difference in M tor the two atoms

N. K. Adam, W. A. Berry, and H. A. Turner The ructure of surface films (Part 10) Two series with structure of surface films (Part 10) liquid expanded films of area (at no compression) different from 48 sq. A have been found, the phenols of 39 sq A and the a-monoglycerides of 70 sq A. The hypothesis of coiled chains for the liquid expanded films cannot therefore be maintained. The evidence is inconclusive in favour of any specific form of a tilted molecule theory, although all forms appear possible. Since the heads appear to contribute to the cohesion in the expanded films, Langmuir's theory that the chains hold the films together against a disruptive force exerted by the heads appears incorrect. monoglycerides form condensed films with closepacked heads, not appreciably rearranged by compression, area 26.3 sq A at no compression. Muller's suggestion that the chains are tilted is not incompatible with the theory of close-packed heads. The condensed film of dodecyl phenol shows hysteresis on compression and decompression.

G. Nonhebel, J. Colvin, H. S. Patterson, and R. Whytlaw-Gray The coagulation of smokes and the theory of Smoluchowski A special cell has been designed for counting smoke particles The coagulation of clouds of ammonium chloride, antipyrin, and cadmium oxide obeys the same general law, which is probably valid for all smokes composed of non-volatile particles. The experimental data agree as closely as those obtained for sols with the theory of Smolu-

chowski

P I. Dee: The mobility of the actinium A recoil atom measured by the cloud method. The mobility of individual actinium A recoil atoms is measured at the instant of their reaching the ends of their recoil tracks. Photographs of four main types of grouped tracks were obtained, corresponding to the double disintegration: actinium emanation  $\stackrel{a}{\longrightarrow}$  actinium  $A\stackrel{a}{\longrightarrow}$ actinium B The relative positions of the origins of these tracks gave the mobility and, in some cases, the life of the A atom. Results obtained for actinium A agree with the usually accepted value for

the mobility, namely, 1.56 cm./sec/volt/cm. The method also gives direct evidence that some of the recoil atoms at the end of their recoil track are uncharged, and the percentage of such neutral recoil atoms agrees with Briggs's value, found by activity distribution methods

A. C. Menzies Shifts and reversals in fuse-spectra. A high-current arc is struck momentarily between The spectrum of copper so obtained has been compared with the low-current arc spectrum, and regularities have been sought on the bases of shifts and reversals. Five, and possibly six, new terms have been deduced, leading to the allocation of 32 new lines. Some of these are identified with terms missing from Sommer's scheme The lines which were reversed have final terms which belong to low levels; for copper they are  $1\,{}^2S_1$  or  ${}^2D_2$  or  ${}^2D_3$  terms. Lines have a tendency to shift as the current increases, for highlevel initial terms having structure (core +s), the lines shift to the red: for high-level initial terms having structure (core +d), the lines shift to the violet, for low-level initial terms, the lines shift in accordance with the Stark effect mainly

C G Darwin The electron as a vector wave spite of the great success of the spinning electron in the theory of spectra there are grave difficulties in its interpretation in terms of the wave theory. These are met by making the hypothesis that the wave of an electron, like a wave of light, has two components. The wave equations are worked out so as to fit the hydrogen spectrum, and this ensures that they will conform to all known conditions of quantum mech-They are found to be unsymmetrical, so that they take a different torm according to what direction of space is chosen as prime axis A general argument from analogy shows that they should therefore be interpreted in terms of a vector, in some degree arbitrary, so as to be invariant in form as well as fact A relativity transformation is applied, so as to identify the doublet effect 'with the Zeeman effect. This encounters the difficulty that it is not at present possible to see what form the Thomas correction should take in the wave theory, and so gives a value for the doublet separation twice as great as it should be.

W. Sucksmith, H. H. Potter, and L. Broadway. The magnetic properties of single crystals of nickel magnetic properties of single crystals of nickel have been examined in the principal crystal planes component of magnetisation parallel to the field was measured by the induction method, whilst the component perpendicular to the field was measured by a torsion method. The existence of directional properties in the crystal invalidates the torsion method for the measurement of the parallel component. The magnetisation and field coincide along the directions of the symmetry axes, the direction of easiest mag-

netisation being along the trigonal axis.

L. N G. Filon: On the second approximation to the "Oseen" solution for the motion of a viscous fluid. We start from the "Oseen" solution as the ' first order' and substitute this first order solution into the terms previously neglected in the exact equations of motion (restricted, however, to steady motion). We then obtain integrals of the modified equations. The new solution contains a certain term in which  $\log r$  appears as a factor, r being the distance from the obstacle. This term, when the torque on the cylinder is calculated, leads to a result logarithmically infinite The force resultants remain finite and the expressions obtained for them from the "Oseen" solution remain unmodified.

C. V. Raman and K. S. Krishnan: A theory of the optical and electrical properties of liquids. The theory is based on the idea that the molecules of the fluid are optically and electrically amstropic, and that, in addition, the polarisation field acting on a molecule in a dense field varies with its orientation relatively to the external field. It offers an immediate explanation why in general an increased density causes a diminished molecular refractivity as calculated from the Lorentz formula. These changes in refractivity and dielectric constant are closely related to a change in the effective optical or electrical anisotropy of the molecules produced by the influence of its immediate neighbours. Similar ideas have been adopted in theories of electric birefringence and of light-scattering in liquids developed by the authors, which have found strong experimental support.

strong experimental support E W R. Steacie and F N C Johnson The solubility of hydrogen in silver The solubility of hydrogen in silver has been investigated from 200° to 900° C, at pressures of 5-80 cm. The solubility first becomes appreciable at 400° C The solubility increases exponentially with increasing temperature. It is proportional to the square root of the pressure. The diffusion of hydrogen through quartz has also been measured from 200° to 900° C. The diffusion of hydrogen through quartz appears to be of a mechanical

nature.

R L. Smith-Rose and R H. Barfield Further measurements on wireless waves received from the upper atmosphere. The results previously published were confined to measurements on waves received from the Bournemouth transmitting station. The investigation has been extended to transmissions from Birmingham, London, and Newcastle Measurements have been made of the mean angle of incidence of the downcoming waves, and from these the effective height of the upper ionised layer has been calculated. By making use of a knowledge of the attenuation of the surface wave over land, it has been possible to arrive at values for the coefficient of reflection of the ionised layer for the various cases dealt with.

#### DUBLIN

Royal Irish Academy, Nov. 30.—P. J. Nolan and Chlan O'Brolchain Observations on atmospheric electrical conductivity in connexion with the solar eclipse of June 29, 1927. Observations made at Llysfaen, Colwyn Bay, showed no variation in conductivity which could be attributed to the eclipse. The relation between the conductivity and the concentration of condensation nuclei was, however, anomalous. An explanation of the anomaly is put forward. Records of ionisation, conductivity, and nucleation under normal conditions are examined, and values for the rate of production of ions in the free atmosphere at different places are computed.

#### Paris.

Academy of Sciences, Nov. 14.-H. Deslandres: Observations on the transit of Mercury across the solar disc, Nov. 10, 1927, made at the observatories of Paris and Meudon All possible instruments at both observatories were utilised, but the atmospheric A general account conditions were not favourable of the work done is given: details of the measurements will be given in a later communication.— G. Bigourdan · The transit of Mercury across the sun observed at the Paris Observatory on Nov. 10, 1927. There was no sign of the ring round the planet noticed in some earlier observations - Maurice Hamy: Observation of the transit of Mercury across the sun on Nov. 10, 1927. On account of the unfavourable atmospheric conditions, only the second interior contact could be observed .- Maurice Hamy: An eyepiece permitting the images to be rotated.—Pierre

proved that immunity against B alree could be conterred on bees—S Schmidt—Contribution to the study of the process of neutralisation between toxins and antitoxins (diphtheria and tetanus). These experiments show that the complex formed by the toxin and the antitoxin in excess react with a new quantity of the toxin differently from free antitoxin—E. Wollman and Achille Urbain. Antigen autonomy of the saicoma of Roux.

#### CAPE TOWN.

Royal Society of South Africa, Sept 28.-P R. v d R Copeman Studies in the growth of grapes (Pt 5). The relationship between the sugar and soluble solids in the juice of the grape is a linear function The slope of the line is closely related to the growth yields of these two factors during the period of ripening. The variations of the constants for different varieties lie within narrow limits and it is possible to obtain a general expression for the sugar in terms of the soluble solids, which is practically independent of changes in locality and season.—M. R. Drennan The dentition of a Bushman tribe The collection comprises the remains of 53 individuals reputed to be Bushmen. Comparative data from the dentition of the Kaffir and a few gorillas and baboons are discussed—D Slome The osteology of a Bushman tribe Skeletons of a tribe of aborigines exhumed at Colesberg by the South African Museum, Cape Town, were examined. The larger group examined is composed of relatively pure Bushmen, more typically Bushman, especially as regards the smallness of their bones, than many other groups which have been described as Bushmen Nevertheless, there appears to be a strain of what might be termed Hottentot blood in them, as evidenced by the narrowing of the skull, and the apparent subnasal prognathism —James Colour and chemical constitution (Pt. 23) The pigments of flowers The gap between the anthocyanidines and their parent, flavylium chloride, has been filled by synthetic derivatives. All the anthocyanidines, except the simplest, possess from three to five different shades, each according to the reaction of the solution.-Lancelot Hogben and Louis Mirvish . Some observations on the production of excitement pallor in reptiles Excitement pallor in chameleons is shown by spinal transection to be determined by a segmental mechanism. The possibility of evoking pallor by stimulation of the cord in isolated segments after the circulation has been cut off indicates that the pigmentary effector organs are under direct nervous pigmentary effector organs are under direct hervous control. It is unlikely that adrenal secretion plays any significant part.—E. L. Gill. Note on a rorqual burned on the Cape Flats. A skeleton of a rorqual (Balænoptera sp.) has been found in surface deposits on the Cape Flats, near Maitland. The circumstances furnish evidence of a comparatively recent rise of level of the Flats in relation to the sea.—Vincent A. Wager. The structure and life history of the South African Lagarosiphons.

SYDNEY.

Linnean Society of New South Wales, Sept. 28.—P. Brough: Studies in the Goodeniaceæ (Pt. 1). The life history of Dampiera stricta R Br. A detailed account is given of the chief phases in the life history of Dampiera stricta R Br.—a representative of the family Goodeniaceæ. Therein are presented organogeny, microsporogenesis, megasporogenesis, female gametophyte, male gametophyte, pollination mechanism, tertilisation, endosperm formation, embryogeny, and conclusions arrived at, as a result of the facts brought out by this investigation.—J. R. Malloch. Notes on Australian diptera (No. 13). This paper deals with the families Sapromyzidæ, Agromyzidæ,

Chloropidæ and Astendæ Numerous keys to both Sixty-four new species genera and species are given are described, distributed as follows .- Sapromyzidæ 34, Agromyzıdæ 6, Chloropidæ 23, Astendæ 1—A. H. S Lucas. Notes on Australian marine algæ The Australian species of the genus Spongo-(Pt. 4). The critical distinction between Spongoclonium clonium and Lasiothalia seems to be that the former is monosiphonius, articulated, without any true cortex, and thus nearer to Callithamnion, while the latter possesses a true cortex and is nearer Crouania object of the present paper is to illustrate so far as material will permit the Australian and Tasmanian species included by De Toni in the genus Spongoclonium. Eight species of Spongoclonium and two species of Callithamnion, which had been included in Spongoclonium by De Toni, are figured

# Needs of Empire.

THE many recommendations submitted to and passed by the delegates of the recent Imperial Agricultural Research Conference have a familiar In substance they are almost identical with those endorsed by the delegates to the Colonial Office Conference held earlier in the year, and in principle they do not differ from those which were submitted to the Imperial Conference of 1926 by the Research Sub-Committee over which Lord Balfour presided, or those contained in the Report of the Imperial Agricultural Research Committee which was published this year Unfortunately, this Conference, like those which preceded it, has not been able to base its recommendations upon an assured income guaranteed by the Imperial Parliament or the beneficiary governments of the It has not even been definitely promised that necessary financial provision will be made for any part of the programme of activities outlined in the recommendations The Conference had to be content with vague hints that support for various schemes of scientific research and technical development would be forthcoming from the Empire Marketing Board, the Department of Scientific and Industrial Research, and other bodies with public funds at their disposal, and the expressed hope that Dominions and other overseas governments might be found willing to contribute to a central fund

The sub-committee of the Conference which dealt with 'Recruitment and Training' emphasised the need for the "immediate reinforcement of activity" to attract candidates of the highest class for the colonial agricultural service and to equip them with They are to be attracted the best possible training by the 'immediate betterment of emoluments, facilities for work, and superannuation arrange-"The inducement in the form of ments." scholarships of any kind" must be considered "wise and fair only if the service be made to provide really good careers." This sub-committee realised that persons with a distinct flair for research must be offered special inducements to take up duties in comparative isolation in any of the existing or proposed links in the chain of the overseas research stations Yet in introducing the Research Stations' Major Walter Elliot suggested that £20,000 per annum was " the sort of figure which one could have in mind in considering the setting up of a station" for the running of which "something like 10 highly qualified men will be necessary as the superior staff."

It is difficult to see how really good careers are to be provided out of this estimated annual cost of running a research station, which is to include the salaries of the staff (superior and minor), equipment and materials, and presumably, travelling expenses—a considerable item. It is not without significance that this estimate passed unchallenged by any member of the Conference Of even greater significance, perhaps, is the fact that throughout the Conference no authoritative and definite statement was made as to what scale of salary was regarded as synonymous with a Undoubtedly there are really attractive career other important considerations to be taken into The intrinsic interest of the work, the facilities offered for and the degree of freedom in research, the scope given for trying-out large scale experiments, will directly influence the choice of a research worker for a particular institution these are the considerations which weigh with those who have already specialised in a particular Those which usually carry branch of science most weight with headmasters who are advising boys on their choice of subjects at the universities are the material rewards offered by the careers associated with their university studies deplorable it may be that very few facilities exist in our boys' schools for biological training, the fact has to be faced that there is little demand from parents for such facilities, the absence of the demand being determined by the present comparative material unattractiveness of biology as a career. Once it is realised by parents and headmasters that not only are trained biologists essential for the development of certain branches of industry, but also that governments and leaders of industry are sufficiently appreciative of the need for such services to offer substantial inducements to those who can provide them, some training in biology will be provided in the schools.

This Conference was given every facility for putting the claims of scientific research before the Empire. Those responsible for the press arrangements did their work most efficiently; it is the members of the Conference who are to blame for not making better use of their opportunities for publicity, the quickest and surest way of stirring the imagination of the public. From beginning to end of the Conference no speech was delivered which dealt arrestingly with the problem of agricultural research as a whole, which attempted to place before the public even a rough estimate of the annual cost to the Empire of the neglect of research, or of the annual yields to the Empire of certain

specific results obtained in agriculture through the application of research

For example, no reference was made to the triumphs of Clouston and Howard in India in connexion with crop production, the amazing rapidity with which application followed research: no estimate was given of the value of the work of Theiler in stamping out the rinderpest in South Africa · the public was provided with no accurate information regarding the additional area placed under cultivation in the Empire as the direct results of experiments in plant acclimatisation and adaptation to soil conditions Similarly, none of the arresting and illuminating statistics were given of the losses sustained by agriculturists through the ravages of insect pests, fungi, unsound irrigation and faulty dramage, or those due to unscientific storage, packing, and transport. Diseases afflicting domestic stock in various parts of the Empire were mentioned, but no emphasis was laid upon the financial aspects of animal disease, or the disastrous effects of cattle epidemics on the social life of the primitive peoples for whose welfare we have assumed responsibility. Again, no clear picture was drawn of the fallow but potentially crop-producing area in the Empire, the possibilities of British tropical and sub-tropical Africa as the greatest cotton-producing area in the world, of the future capacity of Canada and Australia for wheat cultivation, or of New Zealand's exceptional advantages for cattle-raising.

More serious still was the omission of detailed statistics regarding the cost to the various governments represented at the Conference of those departments dealing with the inspection and cure of aling plants and animals. This cost was not compared with the sums made available for applied research, although it appeared to be realised that the results likely to accrue from research are incalculably greater than those from the application of empirical specifics. None of the parliamentarians present took the opportunity of bringing to the notice of the delegates or the country the sums allocated to agricultural research by the United States or by Holland.

It may be urged that information on these several points was already in possession of the delegates. Even if this were true—and it certainly is not—advantage should have been taken of a favourable occasion to place such information before that larger public which is still indifferent through ignorance to the claims of scientific research for more generous treatment. Since it was not, we can only commend to the attention of the Empire Marketing Board the possibility of

bringing some at least of this information before the public through the medium of posters. The work of Lawes and Gilbert, although the beneficence of its scope is not confined to the British Empire, places them on at least an equal footing as Empire builders with the statesmen, soldiers, and sailors whose portraits adorn our hoardings. It may be a vain assumption, but we incline to the opinion that were the facts regarding the beneficial effects of research on agriculture and industry in general better known, the public would not merely acquiesce but demand greater provision for expenditure under this head

From many points of view, however, this Conference was a success It brought together experts and those responsible for the administration of the agricultural services from the overseas parts of the Empire to co-operate with those who bear like responsibilities at home Not only the overseas delegates, but also many of the home delegates, were granted exceptional facilities for making themselves acquainted at first hand with the work of the staffs at most of the important research institutions bearing on agriculture in Britain The series of reports resulting from their joint labours are invaluable contributions to the cause of agricultural research The principles enunciated in the report on "Recruitment and Training" are un-The only pity is that no challengeably sound appendix was attached with information regarding existing methods of appointment and conditions of service in the various home and overseas departments of agriculture and research institutions, together with an estimate of the number of vacancies likely to occur within say the next five years.

In the report on "Tropical and Sub-Tropical Research Stations," the opinion is expressed that "the control of a station should be so vested as to ensure that the work of the institution should not be diverted from a programme of free research" and that such research should be of "long range" and "wide range" character, serving the needs of several territories, reinforcing but neither impairing nor replacing the scientific work properly undertaken by the agricultural department of any government in its vicinity. In addition to the existing stations, namely, the Imperial College of Tropical Agriculture, Trinidad, and the Amani Institute, Tanganyika—lately resuscitated—the provision of five new research stations is indicated. The Australian Commonwealth Government already has a definite plan for the establishment of a station to deal chiefly with animal husbandry, nutrition and pathology, and other stations are contemplated in Ceylon, the Federated Malay States, and an additional centre in East Africa for animal diseases research, although the report indicates that the South African Animal Research Station at Oudersteport must have first consideration as the primary centre for such work. This particular report concludes with a recommendation for the establishment of a central research station to investigate the subject of irrigation, including its engineering, agricultural, chemical, and physical aspects

The third report on administrative matters deals with the establishment and development of effective clearing-houses for the interchange of information of value to research workers in agricultural science throughout the Empire The committee recommended and the Conference agreed to the establishment of three bureaux, a Bureau of Soil Science attached to the Rothamsted Experimental Station, a Bureau of Animal Nutrition attached to the Rowett Institute, and a Bureau of Animal Pathology in London. In addition, it is proposed to set up correspondence stations, for animal genetics at Edinburgh, for agricultural parasitology at the London School of Hygiene and Tropical Medicine, for plant genetics at Cambridge and Aberystwyth, and for fruit production at the East Malling Research Station. It is estimated that the three bureaux will cost £13,000 per annum, and the four correspondence centres £7000 per annum

These last recommendations stirred Sir Damel Hall to the observation, "I grudge every penny of research money which is diverted to the administrator, to the editor, to the indexer, and people of that type. . £20,000 a year represents an estimated cost on an Empire Research Station of the first order" His objection was overruled, both by administrators and research workers. But the principle underlying his objection is sound It is not more administrators of research that are wanted, but more research workers, and although the sum of money involved may seem an insignificant item of expenditure spread over the budgets of the Empire governments, it assumes significant proportions in relation to the expenditure of these governments on true agricultural research can only suggest that the research workers themselves give their serious attention to the diversion of their energies on matters of administrative routine having little bearing on high policy, and be ready to present a working plan of their own for the interrelation of their activities to the next Conference, which is to assemble in Australia in five years'

# Teaching and Research in Organic Chemistry.

Recent Advances in Organic Chemistry. By Prof Alfred W. Stewart Fifth edition Vol. 1 Pp xiv +387. 21s. net. Vol. 2 Pp xiv +382. 21s net. (London. Longmans, Green and Co, Ltd., 1927.)

THE new edition of Prof Stewart's account of recent advances in organic chemistry conveys an immediate impression of the immense current activity in this field, since the author has now found it necessary to expand the work from one volume to two. The rising tide of research papers in chemistry, and particularly in organic chemistry, has, indeed, become something of an embarrassment during the last few years. Despite the introduction of a rigorous scrutiny of contributions, the publication committees of chemical periodicals find difficulty in compressing the material submitted within reasonable limits; librarians are becoming concerned at the increasing demands which are being made upon their housing accommodation; and last, but not least, individual members of chemical societies view with pardonable disquietude their unenviable duty of making pecuniary provision for the printing of a vast output of literature, which for the most part is so highly specialised as to carry little general appeal

Notwithstanding this state of affairs, few chemists will welcome the recent suggestion to observe a ten years' armistice in research. Moreover, although many may be able to accept in its literal sense Prof. Stewart's opinion that if seventy per cent. of the known organic compounds had never been synthesised, we should not miss them, few will regard the task of preparing them as a work of supererogation. Cannot that somewhat pathetic array of 'still-born organic compounds'—the epitaphs of which, according to our author, are inscribed in Beilstein's truly monumental "Handbuch"—be regarded more hopefully as byproducts in the acquirement of experience in research?

Formerly, it was lamented that so little chemical research was being conducted in Great Britain. During the last few years, however, there has been a growing demand in the British chemical industry for chemists with a postgraduate experience of research; and this demand is being fulfilled. Whether suitable candidates for such appointments have gained the Ph D. degree or not, it may be admitted that each one of them in a sense "represents so many new compounds," and thus contri-

butes to the "enormous flood of synthetic material" for which Prof Stewart holds the German university and factory system ultimately responsible. Granted that a supply of properly qualified candidates for industrial posts has been achieved at the cost of several thousands of new but relatively unimportant compounds, we shall scarcely hesitate to pay in full this price of admiralty, although we may regret the necessity of supplementing it by some £125 for the new 18-volume edition of the monumental Beilstein After all, it falls only to a Lavoisier to achieve originality in chemical science, and yet to discover "no new body, no new property, no natural phenomenon previously unknown."

A work of the nature and scope of Prof Stewart's book must inevitably raise many interesting problems concerning teaching and investigation in organic chemistry at the present time. One of the most important of these considerations is the trend of contemporary research It is striking that the old lament over the neglect of organic chemical research should have been succeeded within the space of a few years by a growing criticism of the alleged tendency towards over-indulgence in formal and comparatively barren investigations, which, in Prof Stewart's words, do not "lead to a fresh avatar of the subject." This state of affairs is attributed in part by Prof. Stewart to a transference of the more original minds from organic chemistry, which, on the theoretical side, "is apparently resting on a dead centre of perfection," to the more mobile and spectacular fields of inorganic chemistry and radioactivity. Is it not due also in part to the nature of the Ph.D system, which accounts largely, although by no means wholly, for the greatly increased output of research in recent years ?

The Ph D. degree is granted for organised research under supervision, and is the hall-mark of the potential rather than the mature research worker. The provision of appropriate subjects for research, which shall yield results suitable for publication within a limited time, is often a matter of considerable difficulty; and there is little doubt that much of the formal work appearing in the current journals is an outcome of conditions which often compel an aspiring junior investigator to play for safety. Adjudicators of Ph.D. theses would do well to consider to what extent a bold conception, backed by competent practical work, may be allowed to weigh against a succession of negative results · a sympathetic handling of such cases would do much to lessen the formality of

research work conducted under the ægis of the Ph D. system

Prof Stewart does not despair of the future of organic chemistry. Like many of his contemporaries, he foresees the acquirement of renewed inspiration and vigour from a return to the study of compounds produced by natural methods in plants and animals. There is, indeed, much to be said in favour of an increasing diversion of the activities of organic chemists to investigations dealing with the manifold chemical problems presented by living matter

"For example, nme-tenths at least of our laboratory reactions he outside the temperatureligarts under which the plants and the animals exist, yet plants and animals succeed in producing quite considerable yields of certain materials which we can obtain in the laboratory only with some difficulty It seems not impossible that a study of reactions which can take place at ordinary temperatures and in the absence of violent reagents, might open up an entirely fresh line of development in organic chemistry Our increased modern knowledge of catalysts and their action makes this field much more promising than it once was, and the possibilities involved in the use of colloidal reagents need only be mentioned in order to suggest lines of investigation which could hardly prove unfruitful There is one obvious advantage which would be conferred by a return to Nature such as is here Research of this kind would clearly centre round the very simplest of our known reactions—the addition or removal of the elements of water. for these two processes evidently play a prominent if not a predominant part in the natural syntheses. Thus some incentive would be given to a study of the mechanism of our simplest chemical changes, a subject which would certainly repay a good deal of investigation."

It is nowadays a generally accepted dictum that vitality in teaching is dependent upon a correlated appreciation of contemporary research In organic chemistry, the delicate equilibrium which exists between teaching and research has been disturbed in recent years by several influences, and not least by the remarkable growth of the subject. It is no longer possible to offer a fairly complete conspectus of this branch of chemistry to the advanced student. Excessive teaching, like excessive formalism in research, inculcates the spirit of Beilstein and represses that inborn spirit of adventure which is as essential in the scientific investigator as in the Arctic explorer. Wherefore, the wise teacher selects certain fields of work for special treatment, fixes a judicious limit to the number of his lectures and to the amount of information which he strives to impart, and gives discreet indications of subjects suitable for independent reading and study. Such

a teacher will approve of the plan of Prof Stewart's work, the general character of which will already be familiar to him

The first volume of the new edition contains a treatment, designed for third-year students, of a series of themes which the author regards as a convenient basis for discussing the recent investigations presented in the second volume. themes are not necessarily concerned with recent work, for example, the development of the chemistry of the menthones and other monocyclic camphors has not been traced much beyond 1907. The second volume, to which the title is more particularly applicable, will be appreciated by honours students and research workers who seek compact and up-to-date accounts of carbohydrates, sesquiterpenes, alkaloids, anthocyanins, chlorophyll. depsides, organo-alkalı compounds, abnormal valency, theories of the natural syntheses of vital products, and applications of electronics to organic chemistry The selection of themes for a work of this kind must obviously be determined to a large extent by the particular interests and predilections of the writer; the general tenor of the author's introductory remarks, however, would seem to call, inter alia, for a consideration of recent work on hormones and on the application of catalytic methods in the production of simple organic compounds fruitful field of modern organic chemistry has been harvested by a multitude of labourers, much of the grain necessarily remains in ear, but upon his thrashing-floor of 769 pages Prof Stewart has rendered yeoman service in purging a good deal of it from the superabundant chaff.

JOHN READ.

# Structure of Tropical Cyclones.

Tropical Cyclones By Dr. Isaac Monroe Cline Pp. 301. (New York. The Macmillan Co, 1926.) 21s net.

BEFORE we can explain the origin and life cycle of a tropical cyclone, it is essential that we should have accurate pictures of the air motion at all levels throughout the storm. Dr. I. M. Cline, of the U.S.A. Weather Bureau, endeavours in the work before us to give such a picture for all tropical cyclones that have moved in over the Gulf of Mexico and South Atlantic regions during the twenty-five years 1900–24.

The number of observing stations falling within the storm area was always small, but, with hourly readings of the ordinary meteorological instruments available, each was made to turnish the equivalent of a number of simultaneous scattered observations, by plotting the hourly readings on a single diagram of the cyclone divided into four quadrants. These quadrants were fixed with reference to the instantaneous movement of the cyclone and not according to the points of the compass—thus the two front quadrants lay on either side of the line of instantaneous motion and were separated from the rear quadrants by a line drawn perpendicular to the line of instantaneous motion. With such an arrangement the observations from each station when plotted form a chain running across two or even three quadrants of the cyclone.

The distribution of surface winds, of upper winds deduced from the motion of clouds, and of rainfall, was obtained with a reasonable amount of detail for sixteen storms; and the diagrams, constructed in the manner just described, themselves suggested an appropriate grouping as follows.

- Large cyclones (diameter more than 450 miles) that continued to advance after moving inland.
- II Small cyclones (diameter 300-450 miles) that continued to advance after moving inland
- III Small cyclones which did not continue to advance after moving inland

The observations from all the cyclones in each of these groups were plotted as though they had been made in a single storm In this way three composite cyclones, representative of the three groups, were sketched in great detail. Justification for the method adopted for plotting the hourly observations was then apparent, for where the chains of observations for two different cyclones crossed, the wind directions nearly always agreed well. It seems scarcely possible to improve upon this method of making the most of a limited number of observing stations, and no other part of the world liable to tropical cyclones can at present supply a closer network of well-equipped observing stations near sea-level. The value of the work is greatly enhanced by the publication in full of all the hourly observations.

We may now consider the diagram representing the winds and rainfall in cyclones of Class I. The wind system here depicted differs greatly from the symmetrical whirl around the small central eye of light winds and lowest barometric pressure that one is led to expect from general descriptions of the tropical cyclone. It is only in the two left-hand quadrants, where on the average the winds outside

the 'eve' are least strong, that such motion is found a large part of the front right quadrant contains winds flowing in towards the centre, while in the right rear quadrant the motion is almost entirely parallel to the direction of motion of the centre A considerable amount of convergence results from these last two currents, a little in advance of the line separating the two quadrants, and the distribution of hourly rainfall shows a maximum hereabouts, with a general absence of ram in both rear quadrants as though the right rear quadrant contains a current of air which, ascending and turning to the left, condenses its moisture so as to supply most of the rainfall in the evelone

In the case of the small travelling cyclones (Class II) the above general description applies equally well: the similarity between the wind systems and the position of the region of maximum rainfall is striking and suggests that the observational material used has been sufficiently accurate and abundant to reveal for the first time essential features of tropical cyclones—at least of those passing through this region along normal paths.

Turning now to cyclones of Class III, that is to say, those which failed to pass on inland, the distinctive features of the winds in the two right-hand quadrants are no longer evident, and the cyclone as a whole has much more the character of a circular eddy At the same time the precipitation is no longer localised, the amount in the rear half being at least equal to that which occurs in the front half These storms were found to die out before long, or to move away as very weak, illdefined disturbances. The winds considered so far have been those observed at the surface, and those deduced from the motion of clouds of low and moderate elevation; the convergence between the winds in the right sectors that is so marked at the surface appears to diminish at higher levels, a fact which is in accordance with the suggestion made above that the winds that enter the right rear sector and supply the bulk of the precipitation turn to the left as they ascend above the opposing barrier of the winds of the right front sector. The wind at the height of the cirrus clouds (about six miles), so far as may be judged from the scanty observations of the motion of these clouds available, has little or no relationship with the winds in the lower layers, and shows little regularity. It appears that the direction of motion is often about the same as that of the cyclonic centre in the large travelling cyclones, whereas in the smaller travelling storms it is generally across the cyclone from

left to right — For those cyclones which ceased to advance, left to right movements also predominated, the number of cases where the motion had a component opposite to that of the centre was greater than for the other two classes of cyclone

There is little to add to the above summary, which includes the most striking features of the storms revealed by this new method of analysis. It must be remembered that the results obtained do not necessarily apply to the cyclones of other tropical regions, or to the earlier stages of the same storms It may be assumed that those considered here had nearly all been in existence for several days, they were as a rule approaching the time of their recurve out of the tropical belt of easterly winds into the westerly winds of temperate One would like very much to know the origin of the air that enters the system through the right rear quadrant, but since this would normally arrive from some point between east and south, i e. from the open sea, the construction of trajectories can scarcely be possible, owing to paucity The author was unable to find of observations in the surface temperature records any traces of discontinuity between the converging wind currents, but since both supplies of air must generally have been over warm ocean for many days, this does not prove that they were not in reality of widely different origin when traced sufficiently far back

In conclusion, it may be said that although an explanation is still wanting of the precise mode of origin of tropical cyclones, a notable step forward has been made—Dr Cline is to be congratulated on having produced a collection of facts which must prove indispensable to anyone seeking to provide such an explanation.

E. V. Newnham

# Psychology of Mental Imagery.

Les risions du demi-sommeil (hallucinations hypnagogiques) Par Dr. Eug-Bernard Leroy (Bibliothèque de philosophie contemporaine) Pp. xv + 132. (Paris: Félix Alcan, 1926) 12 francs

THIS is a small book, but an important contribution to the study of mental imagery in general, and in particular of that kind of imagery which is experienced in the hypnagogic state. Many people, just before falling asleep, or waking fully from sleep, pass through a stage in which they have visual (and sometimes other) imagery of a very striking kind. The fact has been known and reported upon in psychological literature for something more than a century; but the interesting problems to which it gives rise have for the most part been cursorily and not very satisfactorily dealt with Dr Leroy limits himself to a psychological treatment of his subject, and puts his book before the public as a contribution to the psychology of hallucinations and dreams. For the physiological and pathological aspects of hypnagogic imagery he believes that methodical experimental work is still greatly needed; but in the present investigation he relies mainly upon his own experiences and those of persons whose sincerity he is able personally to guarantee

In a very careful and detailed description of 'hypnagogic visions,' for which he has drawn upon the available literature as well as cited a number of original accounts, Dr Leroy passes in review and compares with them after-images, phosphenes, entoptic glow (Eigenlicht), and the like He then turns, in a second chapter, to an examination of the conditions of emergence of these images This chapter is closely reasoned and particularly well documented It leads to the important conclusions that such images are frequently hindrances to thought (which may go on in this transition stage between sleeping and waking), and that an appeal to the unconscious to explain their occurrence is "to invoke the deus ex machina of embarrassed psychologists." Psychoanalysts will scarcely agree with this opinion, and, indeed, Dr Leroy omits altogether any consideration of psychoanalytic doctrine from his work.

Chapter in is concerned with the interpretation of hypnagogic imagery, which is here compared with normal memory imagery, the eldetic imagery reported by Jaensch, hallucinatory imagery and illusions. The characteristic most insisted upon is the involuntary nature of the hypnagogic images. The will can only influence them indirectly, and they require for their development a certain degree of psychic automatism.

In the final chapter, hypnagogic images are compared with those of the dream, and the transition from the half-waking state to that of sleep is discussed. The images are spectacles at which we passively assist; the dream is an adventure in which we take part.

Over and above the interest attaching directly to these different kinds of images in themselves, there is the greater interest in the different mental states which give rise to them. In theory and in practice the question is one which concerns both pure psychologists and psychotherapists; and Dr. Leroy's book will be read by both with profit.

# Savovard Highlands.

Rambles in High Savoy By François Gos Translated by Frank Kemp Pp. 169 (London: Longmans, Green and Co, Ltd., 1927) 21s net

THIS is a beautiful book, the sepia illustrations alone giving it a delightful character. They are reproductions of photographs, not by the author but by well-known Alpine photographers, including his celebrated father. Émile Gos There are two prefaces by climbing friends, Mr Geoffrey Winthrop Young and M F. Regaut, president of the French Alpine Club, who was also the commander of the Alpine Corps, the famous 'Diables Bleus,' in the War It may be that many would prefer a simple preface by the author himself, but that feeling is tempered by the pleasure which anything written by Mr Young on his favourite subject must convey, and by the fact that the camaraderie of the War, in which the author served in the Alpine Corps under M. Regaut, has evoked highly interesting remmiscences of the great struggle from the latter in the course of his preface.

As its title implies, climbing in the chain of Mont Blanc is not the main subject of the book; it is more a description of walks and minor climbs in the foothills of that great chain, week-end rambles among them, from Geneva as base of operations. For anyone living at Geneva, or paying long visits to that delightful city, it is indeed ideal. For, as Mr. Young so admirably says, "We cannot think of Savoy as only glacial peaks and passes, nor as . . . alps of summer flowers, nor yet only as romantic villages bright with festal costumes and musical voices. We think of it in single pictures which combine all three simultaneously."

How delightful many of these rambles can be! For they usually culminate in the arrival at the top of some eminence such as the Salève, the Môle, the Brezon, the Aravis, or the Col d'Anterne, from all or any of which we see, growing in immensity and wonder and clearness of detail as we approach the closer, the whole or greater part of the great chain of the most beautiful snow mountains in the world, culminating in the exquisite white dome of Mont Blanc itself, the highest peak of the European Alps, 15,782 feet above the sea. M. Gos writes in a very entertaining manner, and has given us a volume which it will ever be a pleasure to open. Moreover, the author has not suffered from his translator, who has maintained the author's own atmosphere quite remarkably well, and happily gives us the numerous poetic quotations in the original French.

A. E. H. TUTTON.

#### Our Bookshelf.

Economic Biology for Students of Social Science. By Dr Philippa C Esdaile Part 1 Harmful and Useful Animals Pp xv+175 (London: University of London Press Ltd, 1927) 7s 6d. net

THE author rather seeks to disarm criticism by stating in the preface that much ground was of necessity left untouched, and that the critic who cavils at this restriction must be even more ambitious than herself! It is not so much the ground which has not been covered, but the whole point of view from which the book is written which calls for criticism It deals briefly with the structure and life histories of those animal types which students of biology are required to study during their course in social and household science at King's College for Women There are already a number of text-books of zoology which do the same sort of thing, and since this is a specialised course, which has special reference to social science and applied biology, it surely would have enhanced the value of this book if those applied aspects had been dealt with in detail, and the student referred to one of the general text-books for structure and anatomy.

Such important questions as the control of venereal disease, treatment of children for infection with Nemathelmunthes and Platyhelmunthes, and the ridding of houses of insect pests, etc., are not described with any practical detail, and for the average student who does not know where to look for further information, and has little or no general scientific knowledge, the treatment of the subject is too scanty. One feels that a valuable opportunity has been lost of producing a book which might have opened the eyes of social workers, and incidentally of a large section of the general public, to the importance of applied biology. Much might have been done through a text-book for special courses, and by helping the students by a carefully chosen range of reading, but there is not even a bibliography appended. HEB.

Theory of Machines: a Textbook covering the Syllabuses of the B.Sc. (Eng.), A M Inst C.E., and A.M.I.Mech.E. Examinations in this Subject. By Louis Toft and A. T. J. Kersey. (Engineering Degree Series.) Pp. ix +408 (London Sir Isaac Pitman and Sons, Ltd., 1927.) 12s. 6d. net.

ALTHOUGH written primarily as a text-book for students reading for an engineering degree, this volume should prove equally useful to engineering draughtsmen and designers as a reference handbook spanning the gulf which is still sometimes thought to exist between scientific principles and workshop practice. In the first four chapters the authors lay a sound theoretical foundation, and treat such matters as the laws of dynamics and simple harmonic motion with skill and clearness. Their experience as teachers has taught them where the beginner's difficulties generally lie. The rest of the book is concerned with the application of fundamental principles to actual mechanisms in everyday

use, from the simple crank and connecting rod to the gear box and Ackerman steering of a motor-car

On the whole, the ground is well covered, but it is suggested that future editions might contain paragraphs on the reactions exerted by oscillating bodies at their supports, on the properties of the centre of percussion and on the theory of the hammer and pile driver. The theories of toothed gearing and of machine balancing are adequately treated, and the chapter on friction and lubrication, including a discussion of the Michell and ball bearings, is up-to-date.

The book is illustrated with a large number of clear diagrams, while each chapter concludes with a good selection of examples from examination papers and other sources. An appendix on units and dimensions is seriously marred by the astonishing definition of the engineers' unit of mass as the ratio of the weight in pounds of a body to its acceleration in feet per second per second when falling freely; which ratio is stated to be constant.

A. L. RAWLINGS.

Medical Views on Birth Control. By Dr. H. Crichton-Miller, Prof. Leonard Hill, Dame Mary Scharlieb, Dr Arthur E. Giles, Dr. R. C. Buist, Dr. Letitia D. Fairfield, Sir Arthur Newsholme, Sir John Robertson With an Introduction by Sir Thomas Horder. Edited by Sir James Marchant. Pp. xx + 175. (London Martin Hopkinson and Co, Ltd., 1926.) 6s. net.

This book consists of a number of essays by prominent members of the medical profession, with an introduction by Sir Thomas Horder. The latter rightly warns his readers against expecting to find a complete solution to all the problems that have to be considered in association with contraception. The spirit of scientific inquiry has guided the authors, and when personal views are indicated it is quite evident that there is by no means unanimity of opinion. In general, it is recognised that contraception is justified in some circumstances, though one contributor is uncompromisingly antagonistic. To those who seek medical advice on the subject, the question will be a personal one; the general practitioner will therefore find of most interest the chapters on the medical and psychological aspects. The physician has to remember that if he is ever to advise limitation of the family, he must also be prepared to advise a method. Abstinence cannot honestly be recommended, except under conditions which are prohibitive for the average married man and woman. The practitioner will find guidance in the comments and criticisms of other methods given by various contributors.

Standard Methods of the Division of Laboratories and Research of the New York State Department of Health. By Dr. Augustus B. Wadsworth. Pp. xx+704+12 plates. (London: Baillière, Tindall and Cox, 1927.) 34s. net

This book is devoted to a detailed account of the methods used by the division of Laboratories and Research at the Department of Health for the State of New York, situated at Albany, with a branch in New York City and numerous associated

laboratories throughout the State General bacteriological technique, preparation of media and glassware, and diagnosis, for the greater part bacteriological, are fully described, and a large section (326 pp) is given up to the preparation of vaccines and sera. A chapter deals with sanitary chemistry, and at the close of the book a brief account is given of the general organisation of the institute

It is, altogether, a very interesting book and should prove a useful reference to those engaged in public health laboratory work and the manufacture of biological products. One is left with an impression that the institution concerned has developed a high degree of efficiency in routine work, a fact which tends toward making the presentation of the work outlined a little stereotyped.

The Prospective Development of Peru as a Sheepbreeding and Wool-growing Country. By Prof. Alfred F Barker. Pp. xii + 174 + 8 plates. (Leeds · The Author, The University, 1927.) np. PROF. BARKER, at the request of the Peruvian Government, went to Peru in 1926 to study the development of Peruvian flocks and of Peru as a wool-growing country. The present illustrated volume is the report of that visit, with a number of valuable appendices on different aspects of wool. The wool production of the Peruvian tablelands in the high Andes is steadily growing and the number of sheep has doubled in five years. Peruvian wool has many good qualities, and it loses little in scouring because of the cleanliness of the pastures, but the fleece is very light compared with Chilean, Argentine, and Australian fleeces. Prof. Barker discusses the cross-breeding and selection necessary for increase in the weight of the fleeces, and incidentally he points out that the problems involved in these researches make them a valuable field of study in genetics that should appeal to every university. The report is beautifully illustrated, with some of the plates in colour.

The Psychology of Childhood: Normal and Abnormal. By Dame Mary Scharlieb. Pp. xi+194. (London. Constable and Co, Ltd., 1927.) 6s. net.

This little book is by an authority competent to instruct as well as to advise respecting the practical and non-theoretical relationships which should exist between parent and child. Dame Mary Scharlieb with correct intuition speaks of the great burden, yet great honour, of bringing up children, and the necessity of guidance. Parents of all classes will find her conclusions of real help in child-management. Happily, the outlook is not that which prevailed during the War. Those qualified to judge found that the young suffered much from their mothers' privations and anxieties. Children knew neither legend nor fairy-tale. There is a prefatory note by Mr. R. F. Graham-Campbell, a London magistrate, who sees much to commend in a chapter which deals with the action of conscience, the influence of suggestion, and of equable discipline upon juvenile delinquents.

# Cranial Characteristics of Gorillas and Chimpanzees.

In Nature of Feb. 7, 1925, p. 195, Prof. Raymond Dart announced the discovery of a fossil skull of a young anthropoid ape which had been found in a linne-stone quarry at Taungs, Bechuanaland. This discovery brought to light an extinct kind of great anthropoid, which differed from the three living genera—the gorilla, chimpanzee, and orang—in having a long or dolichocephalic skull. After having read Prof Dart's account, Prof L. Bolk, of Amsterdam, drew attention to the skull of a gorilla in his collection which was quite as dolichocephalic as the Taungs skull (Kon. Akad. van Wetensch. Amsterdam, 1925, vol. 28, No 2, p. 1). In the same year, Prof Wingate Todd, of the Western Reserve University, Cleveland, Ohio, informed me that the accepted idea of round-headedness or brachycephaly prevailing amongst gorillas was wrong, several skulls in his collection being dolichocephalic.

In 1926, Dr H. A Harris, of University College, London, examined Lord Rothschild's collection of gorilla skulls, 49 in number, and found that when the shape of the crainal cavity was determined by an exact radiographic method, the head form of the gorilla was highly variable—running from a low dolichocephaly to a high brachycephaly (Amer. Jour. Physic Anthrop., vol 9, p. 157, 1926) The width of the crainal cavity, he found, might be as low as 72 per cent. of the length, or it might be as high as 86 8 per cent., the mean width of all 49 specimens being 79 1 per cent., the intrinsic skull form of the gorilla lying therefore in the upper register of mesocephaly. Thus in the gorilla, which the majority of authorities regard as manifesting a greater structural resemblance to man than any other living form, there is found as wide a range of crainal proportions as is found in any mixed group of human skulls.

As Lord Rothschild's skulls came from widely separated districts, it was possible that the high degree of variability was due to a mixture of local breeds or races. A collection of gorilla skulls, 42 in number, which my friend Dr. N. A. Dyce Sharp has presented to the Museum of the Royal College of Surgeons, shows this is not the case; <sup>1</sup> all the skulls come from one locality, where there can be no question of mixture of races, and the variation in them is just as great as that found by Dr. Harris in Lord Rothschild's collection.

Dr. Sharp was stationed as medical officer in the Ossidinge division of the British Cameroon. In the forest upland of the northern part of this division is found the ultimate distribution of the gorilla towards the west of Africa; Dr. Sharp believes that the habitat of the gorilla extends only a very short distance beyond the Eastern Nigerian frontier. The native villagers of this area hunt and eat both the gorilla and chimpanzee, the gorilla being the more highly esteemed as food. After a village feast the skulls are thrown aside, and it was from the remains of such feasts that Dr. Sharp gathered his specimens. Unfortunately, brains are also valued, and hence some of the skulls were not so intact in the occiput as a

<sup>1</sup> Dr. Sharp's collection was exhibited at a meeting of the Zoological Society on Nov. 15, 1927.

eramologist could desire. Five years ago, Mr. F. W. H. Migeod visited the same area of the Ossidinge district and succeeded in obtaining five skulls of gorillas, which he presented to the Museum of the Royal College of Surgeons, so that I have at my disposal 47 gorilla skulls from the same area on which to determine the variability in size and shape of the skull. The specimens represent both sexes and all ages, from the full eruption of the first permanent molar teeth upwards. The dimensions of the cranial cavity were taken by direct measurements. Dr. Sharp also presented 20 chimpanzee skulls from the same district. They show a much higher degree of uniformity than the gorilla skulls.

In 23 skulls of male gorillas from Ossidinge the mean length of the cranial cavity was 1216 min, the mean width, 95 8 mm, the width being thus 78 8 per cent. of the length, but there was a range from 72 per cent to 88 per cent—from pronounced dolichocephaly to ultrabrachycephaly—The mean cubic capacity of 17 skulls of adult males was 503 cm <sup>3</sup>, varying from 355 cm. <sup>3</sup> to 620 cm <sup>3</sup>. In a local group of gorilla the brain varies in mass just as much relatively as among members of any human community. In 24 skulls of temale gorillas from Ossidinge the mean length of the cranial cavity was 112 2 mm., and the mean width 91 3 mm., the width being 81·3 per cent of the length, but this figure fell as low as 72 per cent. and rose as high as 87 per cent As in human skulls, that of the female is the rounder or more brachycephalic. The capacity of the female skull is much smaller than that of the male—to a greater degree than is the case when human skulls are measured. The mean capacity of the adult female skulls (19 m number) was 425 8 cm  $^{\circ}$ , varying from 370 cm. $^{3}$  to 530 cm. $^{3}$ . The sexual differentiation is more pronounced among gorillas than in any other group of higher primates

The degree of variability in goulla skulls is even more pronounced when external measurements are taken in a manner which gives dimensions comparable with the length and width as usually taken on human The external length varied, in male skulls, from 113 mm. to 155 mm, the mean being 138 3 mm., while the mean width fluctuated between 92 and 101 mm., the mean being 97.2 mm. The width thus varied from 60 per cent. of the length to 79 8 per cent., the mean cephalic index being 66. In female skulls the mean width was 68.6 per cent. of the mean length, the proportion varying from 61.7 to 80.6 per cent. There is even a greater variability in the form of the face of the gorilla. In the Ossidinge breed it varies from being short and wide to long and narrow—a variation of a similar kind being also noticeable in all human communities. The Kivu gorilla, which represents the most eastern distribution of the genus, shows the same variability in form of face.

It is interesting to compare measurements taken on Dr. Sharp's collection of chimpanzee skulls with those taken on gorillas from the same district. In 10 male chimpanzee skulls the cranial capacity varied from 325 cm.3 to 430 cm.3, the mean being 368 cm.3. The range was thus 105 cm.3 compared with 265 cm.3 m the male gorilla skulls. In female chimpanzee skulls the capacity varied from 330 cm.3 to 395 cm.3, the mean being 358 cm.3, and the range 65 cm.3, compared with 160 cm.3 in the corresponding group of gorilla skulls. The mean difference between the capacity of male and female chimpanzee was only 10 cm.3, the sexual difference among gorillas being 76 cm.3. The length of the cranial cavity in 10 male chimpanzee skulls varied from 98 mm. to 108 mm, the mean being 105.7 mm., while the width fluctuated between 86 mm. and 92 mm., the mean being 89.3 mm. The mean proportion of width to length was 84.5 per

No. 3034, Vol. 120]

cent., the chimpanzee being thus markedly brachycephalic. The index or proportion varied from 796 to 90 1, a range of 10.5 units, as compared with 16 1 units—the range of variation in the skulls of male gorillas. If external measurements are compared, the skull of the male chimpanzee has a width which is 75 per cent. of the length, but it may fall to 71 or rise to 78 per cent. In female chimpanzee skulls the internal length varies from 98 mm. to 114 mm, and the width from 86 mm to 93 mm., the mean length being 1055 mm, the mean width, 888 mm. The mean width is thus 84.1 per cent. of the mean length, but the proportion varies from 789 to 91.8 per cent. Thus there is no significant difference between the form of the cranial cavity of the male and female chimpanzee, whereas in gorillas the difference is of a decided character.

One other point relating to the differentiation of species amongst gorillas and chimpanzees may be mentioned here. Lord Rothschild has directed attention to the external characters which distinguish gorillas of one district from those belonging to other districts. There should be no hesitation in distinguishing a gorılla of the western frontiers of Uganda from one native to the eastern frontier of Nigeria, but when I have sought in skulls for recognition marks, I have hitherto failed to find any certain distinctive and constant mark. It is quite true that it is possible, in a certain proportion of cases, to distinguish the skull of a Kivu gorulla from those from other districts, but for one which can be picked out from a miscellaneous group there are four which cannot be identified, except by their labels. I am sure Lord Rothschild is right in dividing both gorillas and chimpanzees into local races or subspecies, but the degree of differentiation has not yet affected the cranial or dental characters to a degree which permits the racial identification of the majority of individuals. ARTHUR KEITH.

Royal College of Surgeons, London, W.C.2, Dec. 5.

#### Consistent Dynamical Units in Solar Radiation.

SIR NAPIER SHAW—facile princeps, in the group of disheartened but persistent advocates of reform in our heterogeneous units of weight and measurement—proposes in volume 1 of his "Manual of Meteorology" a consistent dynamical unit based upon the C.G.S system for records of solar (likewise terrestrial) radiation. The unit he suggests is the kilowatt per square dekametre per minute, that is, 0 0143 of a gram calone per square centimetre per minute. It will perhaps be granted even by those who favour the retention of the calone that the minute is not a desirable interval; and that it will be better to use the hour. Thus we are in agreement with electrical measurements of light and power. A gram calorie being approximately 4:183 joules, it will require 860.300 calories to equal 1 kilowatt hour.

This unit equals 3411 British Thermal Units, and it is worth noting that there is constant hability to confusion here with British Trade Units. Some teachers still prefer to express work in foot-pounds, and energy output in horse-power, but even these must grant that the horse is fast disappearing from highways and is even replaced on farms by tractors. Hence in a few years this unit h.p. (0.746 kilowatt) will go the way of barley corns, once sub-multiples of the mich.

It would seem to those desiring simpler fundamental units that Sir Napier Shaw has a strong case when he says that the gram calorie per square centimetre per

minute "is only tolerable when radiation measurements are regarded as belonging to a separate physical compartment and the transformations of energy in the atmosphere which are the natural results of radiation are ignored, although the comprehension of those transformations is the very purpose of the measurement of solar and terrestrial radiation so far as meteorology is concerned."

The use of the new unit has been opposed on two grounds; namely, (1) that uniformity is desired; and (2) that future measurements may be easily compared

with older results.

It will appear below that uniformity is best secured by a unit which is not confined to heat capacity alone. As for the second objection, this would be a case of bringing the colours back to the regiment instead of bringing the regiment up to the colours. The old values are easily read, remembering that one calorie per square centimetre per minute equals 1·161 kilowatt hours per square dekametre. (The square dekametre is 1076 square feet.)

A good start in the use of the new units has been made by Dr. H. H. Kimball (Monthly Weather Review, April 1927, p 157), who has assembled values for different observatories. As the table may not be generally known, it is here reproduced.

AVERAGE ANNUAL AMOUNT OF SOLAR ENERGY RECEIVED ON A SQUARE DEKAMETRE OF HORIZONTAL SURFACE IN KILOWATT HOURS

ALEXANDER McADIE.

Blue Hill Observatory, Readville, Mass.

#### Absorption of X-rays in Various Elements.

In a recent letter to Nature (Nov. 12, p 695), Dr. E. Jonnson concludes from his measurements on the absorption of X-rays over a wide range of wavelengths that the so-called 'jump'  $\delta_K$  of the absorption coefficient in passing the K-absorption limit is given by

$$\delta_K = \frac{E_K}{E_{L_1}},$$

where  $E_K$  and  $E_{L_1}$  are the energy levels corresponding to the K- and the  $L_1$ -levels respectively. Mr. Johnson does not define  $\delta_K$ , but I assume that, in accordance with current practice,  $\delta_K$  is the ratio of the fluorescent absorption coefficient infinitely near to, but on the short wave-length side of, the K-limit to that coefficient infinitely near to, but on the long wave-length side of the K-limit.

A relation substantially identical with this was suggested by the writer some years ago (F. K. Richtmyer, Phys. Rev., vol. 23, p. 292, Feb. 1924). But it is difficult to harmonise this suggestion with our present concepts of atomic structure. If we accept the usual quantum-photoelectric picture of the absorption of X-rays, it follows that this ratio  $\delta_K$  is numerically equal to the ratio of the number of  $(K+L+M\ldots)$  photoelectrons to the number of  $(L+M\ldots)$  photoelectrons expelled by a beam of X-rays of wave-length  $\lambda < \lambda_K$ , where  $\lambda_K$  is the wave-

length of the K-limit. If, then,  $\delta_K = \frac{E_K}{E_{L_1}}$ , it follows at once that the relative numbers of K- and of L-photo-electrons must be independent of the relative numbers of

K- and of L-electrons in the atom. This, if true, would be a very surprising result, for it is more or less obvious, a priori, that the probability of the photoelectric expulsion of an electron from a given group should depend, in part at least, on the number of electrons in that group. Several different investigators have derived expressions on theoretical grounds (for a summary, see F. K Richtmyer, Phys. Rev. vol 27, p. 1, 1926 Also abid., Dec 1927) showing that the probability of the photoelectric election of an electron from a level in which the binding energy is E and containing n electrons is proportional to  $nE^2$ —a prediction which, however, agrees only qualitatively with experiment.

A precise experimental check of any theory of the absorption of X-rays is rendered very difficult by the fact that, of necessity the measured values of absorption coefficients must include scattering at present no means, either experimental or theoretical, of determining, with anything like acceptable accuracy, the scattering coefficients at various wavelengths by means of which to determine from the measurements the actual values of the fluorescent absorption coefficients As an illustration of the ambiguity in measuring  $\delta_K$  may be mentioned the fact that  $\delta_K$  for silver is either 6.4 or 6.0 according as the (mass) scattering coefficient is taken as 0.8 or 0.2. For gold, the respective values of  $\delta_K$  are 6.4

However, there is no reason to reject an experimentally determined relation just because it happens to conflict with theory. Accordingly, the full text of Mr. Jonnson's paper will be awaited with interest

F. K. RICHTMYER. (Cornell University.)

Gottingen, Nov. 21.

#### The Mechanism of the so-called 'Posterior Sucker' of a Simulium Larva.

IN NATURE of July 30, p. 154, Dr. R. J. Tillyard criticised my letter that appeared in the issue of April 23, p. 559, under a misapprehension. The delay in reply has been due to the fact that until my arrival ın Edinburgh I was not able to consult Tonnoır's paper in Ann. Biol. Lacustre, 11, p. 163 My reference to it in the first letter was based on information contained in Dr. Puri's paper (Parasitology, 17, pp. 295-369;

My object in writing my letter in Nature of April 23 was not to lay claim to a discovery, but to lend support to Tonnoir's views regarding the function of the so-called 'suckers' of the Simulium larvæ. The publication of Dr. Puri's paper showed that the work of Tonnoir was not fully accepted, and I considered that further remarks on the subject were desirable. It was a matter of great pleasure to me that my observations corroborated Tonnour's account in all essential

respects.

Dr. Tillyard has objected to my use of the word 'strong' for the muscles of the posterior 'sucker,' and in support of his arguments has referred to Dr. Puri's figure (pl. vin, fig. 10). I wonder if Dr. Tillyard took the trouble to study carefully this figure and to understand it from the account given by the author. Besides mentioning a number of slender muscles, Dr. Puri (p. 321) points out that "a very stout muscle originating dorsally from the anterior end of the seventh segment, and dividing into two strands, is also attached within this space." Moreover, while discussing the action of the posterior appendage. Dr. Puri (p. 311) says that "my observations, however, show that there are fairly strong muscles connected with the centre of the disc," etc. (Italics are mine.)

In support of his view regarding the function of the sucker' Tonnoir has said, "La dissection montre, d'ailleurs, qu'il n'existe pas de faisceaux musculaires destinés à la formation de cette coupe." Dr. Tillyard justifies this statement by pointing out that "Tonnoir had the blepharocerid larva in mind (on which he was working at the time) when he wrote" this. In his paper Tonnoir gives no indication of this fact, and, even if it be so, to me such comparisons between the structures of two different organisms of a very different build seem misleading.

There is one more point to which I must refer here. I have described an abnormal mode of progression and not "the true method of progression." The larvæ were allowed to crawl on a wet slide and the progression was effected, under the conditions, without the help of the posterior appendage. In a letter to NATURE I could not discuss my observations in detail and I thought it appropriate to illustrate the salient points by the photograph published on April 23. I hope to discuss in detail, at some later date, the function of the organs of attachment in the fauna of torrential streams. SUNDER LAL HORA.

Zoological Department, University of Edinburgh, Nov. 14.

#### Partial Transit of Mercury in May 1937.

THE older text-books indicate a transit of Mercury on May 11, 1937. Thus, Rev. S. J. Johnson, in "Echpses and Transits in Future Years" (1889), p. 6, says: "Mercury on the sun from 8 h morn. to 9.2 h. approximately." On the other hand, Prof. S Newcomb, in his paper on transits of Mercury in vol 1 of Papers of the American Ephemeris, describes the event as a near approach. It does not appear, however, that this statement was the result of accurate computation; it was merely an inference from the large diagram of transits contained in the paper.

I have lately made a computation from Newcomb's tables of the sun and Mercury; I obtain the result that, while there will be no transit in the northern hemisphere, a portion of the planet will encroach on the sun as seen from some southern stations. time that I chose for computation was May 11.37755 U.T. The actual least distance of centres was a few minutes earlier. I obtain true heliocentric longitude of Mercury referred to mean equinox of date 230° 12' 12" 86 latitude – 19' 15".81, log. radius vector 9 6575860. True longitude of sun 50° 15' 23".78, latitude + 0 07", log radius vector 0.0044402; true semidiameter 949" 84. Least distance of centres (geocentric) 957" 96. The apparent least distance is 1" 65 greater through differential aberration Since the differential parallax is 7'' 1 and Mercury's semidiameter 6''.0, there is an overlap at the point of greatest phase of 13''.1 – 8''.12 – 1''.65, or 3''.33. If the tabular places are exact, there will be a small encroachment of the planet on the sun as seen from Port Elizabeth, but probably not from Cape Town. The occasion will be a favourable one to search for a ring round the outer portion of Mercury, due to refraction in its atmosphere. In England the least distance of Mercury from the sun's limb will be about 6", so it should be possible for spectroscopists to see it projected on the chromo-

Such partial transits of Mercury are very rare, occurring only once in several centuries. When they occur, we get two May transits twenty years apart; thus there is another short transit in May 1957, this time at the sun's northern limb. It happens that the other rare event of two November transits at an interval of six years also occurs this century, in 1993 and 1999. In consequence, the number of transits in the century, fourteen, is slightly above the average.

In the course of this work I detected an error in the Nautical Almanac for 1878, p. 402; the least distance of centres of sun and Mercury should be 4'47" 4, not It is well to note this, as it is likely to confuse those who are using the 46-year cycle to predict the circumstances of future transits. I used methods of this kind in my paper on transits of Mercury in the *Observatory* for 1894, p. 394 I there obtained 16' 1" as the least geocentric distance of centres in 1937; this estimate took no account of perturbations, but its close agreement with my present more careful result serves as a check on the latter.

A C D. CROMMELIN

#### Mathematical Theory of Relativity.

THOSE results in the mathematical theory of relativity that have received experimental confirmation are connected with problems that might be classified as the single-line type. These problems are in the same category as those discussed in particle dynamics and

their analogues in geometrical optics.

When, however, we come to problems involving a congruency of lines, logical difficulties arise. It seems clear that we can no longer identify any one of the fundamental co-ordinates with 'time' Thus, consider the question of 'volume.' In the classical theory the element of volume is invariantive. In the case of a four-dimensional continuum, it is the fourfold element that is invariantive, whereas the threefold element is defined by the four components of a tensor.

Now, taking the four-dimensional continuum, the ground-form of which is given by the equation,

 $ds^2 = dx_4^2 - dx_1^2 - dx_2^2 - dx_3^2,$ 

we readily obtain a group of a type similar to that of the rotations about a point in Euclidean geometry, which forms the basis of the treatment of the angular velocities of a rigid body. This, however, simply provides us with one fourfold continuum suffering displacement through another, which is not exactly what is required. We have, in fact, introduced a fifth variable, namely, the parameter by which the infin-tesimal transformations of our group are defined. Thus a supplementary relation, preferably of a differential type, is needed to define our moving system, and this must be invariantive in character. The abovementioned parameter will then furnish a time measure for the system as defined. It seems that in only some such way can we provide a logical geometrical picture of rotation, which is an undoubted physical pheno-

At present difficulties arise through the necessity of using the old technical nomenclature in connexion with the new ideas, and thus often for purposes for which it was not strictly intended. In the case of the historical dispute concerning the measurement of 'force,' the difficulties were eventually dissipated by the emergence of the concepts of 'momentum' and It may be anticipated that something similar might happen with regard to the new theories.

Einstein has lately indicated that he has not found the new differential geometry any more capable of giving the required generalisation of the electromagnetic equations than the older Riemannian geometry, though the former was introduced with this purpose in view. May it not be that too close an analogy with Maxwell's equations has been contemplated? Thus one would suggest the introduction of a time measure for the electromagnetic field by some such general method as indicated above, together with some compensating addition to the set of equations.

#### The Oogenesis of Daphnia by Intra Vitam and Post Vitam Staining.

RECENTLY the claims of neutral red as an intra vital stain for the Golgi bodies have been urged by

Dr. Parat and his pupils.

Daphnia is easily stained intra vitally in weak solutions of neutral red, the stain colouring these animals bright pink in a few hours. Janus green solutions also work perfectly on such fresh-water crustaceans.

We have found that the growing oocytes of Daphnia exhibit bright red granules after staining in neutral red. In the gland and gut cells also, red granules are conspicuous. The youngest oocytes and oogonia do not exhibit such red granules, the latter appearing at

the time of yolk formation.

Daphnid ovaries fixed in Champy's fluid and stained in iron alum hæmatoxylin show empty vacuoles, with a chromophile cortex, which correspond in position and size with the neutral red granules of the intra

vitally stained specimens.

These vacuoles are merely the familiar yolk spaces within the Golgi bodies as described by Ludford, Brambell, the present writers, and many other authors. The dictyosomes or Golgi bodies of the oogonia before the inception of yolk formation stain pink in neutral red, and it is only when the yolk spaces are formed that their acidic contents stain bright red in neutral red.

The mitochondria stain green in Janus, and occupy the usual position in the early and growing eggs.

These results may be confirmed by the Nassonow and Da Fano methods, although the latter causes much shrinkage, and is extremely capricious on crustacean material.

With the assistance of Miss Kennelly, we have tried these stains on Limnæa and certain other fresh-water The neutral red will stain a Limnæa bright pink in a few hours, and the molluses appear to

live quite happily in this condition.

We have been unable to confirm Mme. Karpova's claims as to a 'vacuome' in mollusc spermatocytes. On the contrary, neutral red vacuoles only appear during oogenesis, as already described in Patella and Limnæa by Ludford, Brambell, and one of the present ANNIE GLENDON HILL.

#### Variation of Intensity Ratios of Optically Excited Spectrum Lines with the Intensity of the Exciting Light.

THE principle referred to by Prof. Wood in his letter to NATURE of Nov. 19, that the product of a two-stage absorption increases at first as the square of the intensity of the light, that of a three-stage absorption as the cube, and so on, is evidently capable

of wide application

The necessary data for the examination of the photographic action from this point of view have now been obtained at this Observatory, where the principle was recognised some time previous to its statement by Prof. Wood (see *Proc. Roy. Soc. Edin.*, 47, p. 47 footnote; 1927). The results show a striking similarity to those found by Prof. Wood for mercury vapour. The latent image (in so far as it is developable) is made up for the most part of a slowly developing image resulting from a two-stage absorption process, and of a rapidly developing image formed by absorption in three or more stages. By an extension of the principle to the effects of varying the exposure time, the emissions as well as the absorptions may be examined; in this way the three-stage absorption product is found to develop readily only when accompanied by one intermediate emission—unless this emission occurs, the product is a so-called reversed' grain

It may be noted that while grain counts of fully blackened grains refer to both the two stage and the three or more stage absorption images, counts of grains containing one or more 'nuclei' after partial development refer to the three or more stage

absorption product only.

These results, if accepted, would place the photographic action among the phenomena of phosphorescence.

Royal Observatory, Edinburgh, Nov 22.

#### Misleading Uses of the Term 'Self-Adaptation.'

May I be permitted to direct attention to the use of loose terminology that occurs all too frequently even in some important scientific articles? particular term that I refer to is that in which plants and animals are said to have adapted themselves to some particular environment, etc.

Thus in an article in NATURE of Nov. 26, p. 786, giving the substance of a paper read by Dr. C. M Wenyon to the Royal Society of Edinburgh, flagellates are said to have adapted themselves to life, etc., and this expression is used in the article no less than three

Such expressions as animals adapting themselves, and shade-loving plants, etc., and even the term mimicry, are highly undesirable, though the last term is far too well established for any protest to be effective now. The reason why they are undesirable is that they savour of anthropomorphism, and in these days when one hears so much about natural selection from all quarters, it is imperative to guard scientific terminology most carefully.

These expressions, of course, do not cause any misconception in the mind of the trained scientist, but they are too frequently copied in text-books, elementary and otherwise, and there do a great deal of harm by giving the young student and the lay reader a totally wrong impression. Again, it becomes a very difficult task for the teacher to discourage the use of expressions of this kind amongst his pupils when they

are used by leading authorities.

Such is the desire of the everyday citizen for scientific knowledge at the present time, that no scientific writer is free from the possibility of having his articles appear in a popular form in general literature; the responsibility for accuracy on his part is therefore great.

A. G. LOWNDES.

Marlborough College, Wilts.

#### Regularities in the Spark Spectrum of Silver.

ACCORDING to the theory of Hund, the fundamental terms of the spark spectrum of silver would consist of a deep  ${}^1S_0$ -term (combination  $d^{10}$ ) with metastable triplet and singlet D-terms ( $d^9\ s^1$ ). These would combine with a set of triplet and singlet F,  $\overline{D}$ , and Pterms  $(d^9 p^1)$ .

I have been able to identify the fundamental triplet and singlet D-terms, and the second set of terms. Higher Rydberg sequence to the fundamental D-terms has also been obtained. It has thus been possible to calculate the approximate value of the metastable D-terms. The deepest  $^3D_3$ -term has a value of about 138,000, corresponding to an ionisation

potential of 17 volts, the consecutive differences being  $1577(^3D_3 \cdot ^3D_2)$ ,  $2999(^3D_2 \cdot ^3D_1)$ , and  $2306(^3D_1 \cdot ^1D_1)$ The arc spectrum of silver is a purely doublet

spectrum, the metastable inverted D-terms which are such prominent features of the analogous metals-copper and gold being either totally absent or failing to occur under the usual conditions of excitement. The fundamental  ${}^{1}S_{0}$  will have thus a much higher value than  ${}^{3}D_{3}$ . For Cu<sup>+</sup> the corresponding value has been calculated by Shenstone to be 22,224. Taking the corresponding value for silver to be 40,000, the ionisation potential of Ag+ comes out to be about 22 volts, subject to the approximate nature of the assumptions made in the calculation

K MAJUMDAR

Physics Department, Allahabad University, Allahabad, India, Nov 3.

#### Solution of the Equation $\sin \theta/\theta = c$ .

MAJOR A. E. LEVIN (NATURE, Nov. 26) points out that the usual solution of the above equation by the method of successive approximations is more simple than that which I gave in NATURE of Oct. 1. The expression which I gave is only intended as a first approximation, and as such should only be compared, if comparison is necessary, with the first approximation  $\theta_a = \sqrt{6d} = \sqrt{6(1-c)}$ , in the method he

If such comparison be made when 1/c = K = 1 072502 and K=1 5707963, my expression gives errors + 5′ 32″ and + 1° 6′ 49″, whilst  $_{1}\theta_{a}$  gives errors - 22′ 48″ and -5° 23' 54", the true solutions being 36° 52' 12"

and 90°.

It will be seen that over this range the relative error resulting from the use of my expression is about one-fifth of that with the expression  ${}_1\theta_a$ . This meets that part of Major Levin's letter that refers to my original remarks, which I confined to the range  $0^{\circ}$  to  $5^{\circ}$ .

There are, however, other advantages that make my expression worth consideration as a first approximation. Thus, if c = 0.1909860 and d = 0.8090140, my expression gives the answer with an error  $+2^{\circ}17^{\prime}49^{\prime}$ an error that can be removed by a further stage of approximation, the true answer being 150°. V. NAYLOR.

H.M. Dockyard School, Devonport.

#### Calendar of Discovery and Invention.

In this week's issue appears the last group of notes of the Calendar of Discovery and Invention which I have had the pleasure of contributing to NATURE during the past year. This calendar has aimed at recalling some of the most important advances in science and some of the principal mechanical inventions, and is supplementary to the Calendars of Scientific and Industrial Pioneers which appeared in 1921 and 1922. In the preparation of these notes I have received assistance from many sources, and I should like to take this opportunity of thanking Dr. W. Clark, Mr. A. Gomme, Mr. B. A. Behrend, Dr. R. T. Gunther, and Sir Charles Sherrington for their kindness in placing information at my disposal. The late Dr. Daydon Jackson also kindly sent several interesting notes, which were included in the Calendar, referring to botany and the Linnean Society. Edgar C. Smith.

Riddleswood, Selcroft Road. Purley, Surrey.

#### Reform of the Calendar.

THE appointment of a special committee of mquiry into the subject of calendar reform was the natural result of a movement which had been gathering force for some twenty years at least. Before the outbreak of the War, chambers of commerce and other bodies had agreed in expressing a strong desire for amending certain defects and inconveniences in the existing calendar, and on the termination of the War and the establishment of the League of Nations, it was almost inevitable that a matter so largely bound up with the commercial and industrial life of the nations in general should be taken in hand by the League.

The questions involved being concerned with religious as well as commercial interests—especially as regards the growing desire for the stabilisation of Easter—the League's Advisory and Technical Committee for Communications and Transit, which undertook the discussion of the matter, invited the Holy See, the Œcumenical Patriarch of Constantinople, and the Archbishop of Canterbury to nominate representatives to assist the Committee at a meeting held at Geneva in August 1923, and at the conclusion of that meeting a special committee of six (including the three ecclesiastical representatives) was appointed to review the whole situation. The result is the report and its ap-

pendices now before us.1

The Committee had a large mass of material available for discussion. Prior to its opening session, the general secretary of the League had communicated to the various governments and religious authorities a resolution passed by its Advisory and Technical Committee for Communications and Transit, and invited comments and observations which might be of help in the inquiry In addition, the special committee itself distributed a questionnaire to a large number of international, educational, industrial, and other organisations, and at its second session it heard Dr. Adolf Keller, representing a large number of Protestant religious communities, and also many of the chief rabbis of Europe and America. The Committee further received more than 180 schemes for reform from private correspondents. All this material has been very carefully sifted and classified and is set out in three annexes. The first deals with calendar reform in general. The second with the Easter problem, and the third summarises the proposals received under nine main groups

The report itself contains a historical survey of the circumstances leading up to the appointment of the Committee and a clear statement of the chief defects of the existing calendar. The Committee resolved to treat the questions of general reform and of Easter separately, and the report is divided under

these two headings.

As to general reform, the Committee was instructed 'not to consider any changes in existing conditions unless such changes were definitely demanded by public opinion for the improvement

<sup>1</sup> League of Nations, Geneva. London: Constable and Co., Ltd., 1926 and 1927.

of public life and economic relations "Accordingly, all proposals which involved tampering with the year, either as regards its commencement (such as a suggestion that this be advanced to the epoch of the winter solstice) or its length (including proposals to correct a small outstanding error in the Gregorian year, and to obviate difficulties arising from the 365th day by the adoption of a leap week at appropriate intervals, etc.), were ruled out. Full consideration, however, was given to suggestions for equalising the divisions of the year as well as to proposals for rendering the calendar perpetual by introducing a principle of dies non or blank days.

As regards the divisions of the year, suggestions for reform mostly follow one of two courses (treated as three in the report). The first is to modify slightly or readjust the lengths of the present months so as to equalise the quarters; the second is to divide the year into 13 months or periods of four weeks each. The respective advantages and disadvantages of both methods are clearly set out in the report. Regarded from the purely business point of view, and quite apart from any consideration of the great inconveniences which changes must inevitably involve in other respects, the real point at issue is whether the quarters or shorter divisions of time based on the week are of primary importance. The replies to the Committee's questionnaire indicated that the present twelve-months year is in general preferred. The Committee has, however, merely recorded the facts without making any recommendation, though it has directed attention to the growing tendency among private organisations to make use of an auxiliary calendar of their own, especially that based on thirteen four-weekly periods as adopted by the British railways and many American organisations.

Under both of the proposed lines of general reform referred to, the odd day (two days in leap years) over and above fifty-two weeks remains an obstacle to perpetuity in the calendar, and it is strongly urged by many supporters of both systems that such days should be excluded from the regular sequence of the days of the week. This proposal has met with very strong opposition in certain religious quarters, and here again the Committee has simply recorded the facts, though urging a fresh examination by the opposing religious bodies

of the principle of a blank day.

As regards proposals to stabilise the festival of Easter, the Committee is rather more definite in its expression of opinion: and in view of the almost universal desire for this measure of reform, such an attitude is natural. It is pointed out that most of the replies apparently favour the second Sunday in April for Easter Day, but it is suggested as a slight modification of this proposal that the Sunday following the second Saturday might be preferable, so as to avoid the clashing of Passion Sunday and the Feast of the Annunciation which would occur whenever Easter fell on April 8. It is, however, emphasised by the Committee that Easter is essentially a religious festival, and that the approval of the

Churches is needed before the proposed reform can be properly effected. From a perusal of the documents contained in the report, it appears that the authorities of the Eastern and Anglican Churches have already accepted the principle of stabilisation, but require as a condition that the change should take place by general agreement of the Churches. The Roman Church admits that there is no objection to the change on dogmatic grounds, but asserts that such a departure from ancient tradition and custom, even if the change were demanded by the general good, could only be considered on the advice of an (Ecumenical Council The opinions expressed by the various Protestant communities are almost universally favourable to the proposal.

Taking the report as a whole, it may be said that its chief value lies in its very clear presentation both of existing defects and of the main trend of critical thought which aims at reform. The pros and cons

of the schemes submitted are fairly set forth, so that anyone interested is able to acquire a knowledge of the points at issue very quickly. But it seems important to emphasise the view of the Committee that public opinion in general is as yet nowhere sufficiently informed to press for definite action in any particular direction of general reform (that is. apart from the Easter question). For example, the replies received from the various governments. show that only certain scientific bodies have as vet. been consulted, and it is suggested that now the preliminary eliminations have been made, the principles underlying the main groups of proposals. should be carefully studied and explained, and that to this end the investigation should be organised in each country on official or semi-official lines. It is the view of the Committee that until this is done an international conference to effect general reform could have no chance of success.

# The Second Greenland Expedition of the University of Michigan.

By Prof. WILLIAM HERBERT HOBBS, Director.

THE first Greenland Expedition of the University of Michigan was carried out in the summer season of 1926 within the Holstensborg district of south-west Greenland and was preliminary only in its nature. It was to pave the way for the second expedition, that of 1927-28, the primary object of which was to be to set up upon a mountain, as near as might be practicable to the inland-ice of Greenland, a meteorological and aerological station, and to continue observations there for the period of at least a year. Some account of the first expedition appeared in the January number of 1927 of the Geographical Review. The second expedition left Copenhagen on June 4, 1927, by Danish Government steamer a week behind the scheduled sailing of this vessel The expedition reached Holstensborg, south-west Greenland, on June 20, and two days later left for the Söndre Stromfjord (Kangerdlugssuak) on the Hvalrossen, a 22-ton motor schooner hired from the Danish Government at Holstensborg

On the way down the coast, one of the worst summer storms for this coast in many years was encountered, and the little craft was driven for shelter to a small inlet, the Inugsugtussok, where the expedition was storm-bound for seven days. On June 27, during a temporary lull of the storm, the little craft ventured out, but after being buffeted for several hours was compelled to put back after two boats had gone adrift, but, fortunately, had been recovered.

On July 2 the expedition reached its objective at the head of the great Sondre Strömfjord, one of the longest and largest fjords in the world, and in its lower reaches probably unsurpassed for grandeur of scenery. The expedition was fortunate in finding at the head of the fjord not only a suitable landing-place and base site supplied with running water, a rare thing in Greenland, but also in the immediate neighbourhood was found a mountain 1290 feet in height, easy of ascent and dominating the entire

horizon. Only fifty feet below the summit is a lake of excellent water, and the gradients were such as to make the transport of material to the summit not too difficult. This mountain has been named Mount Evans, and upon it has been located the aerological station of the expedition.

After the first organisation of the camp and protecting the stores from the weather, the heavy task of moving the building material to Mount Evans was at once begun. Lumber, supplies and equipment, the heavy radio batteries and generator, provisions for the year, and fuel for the winter, had all to be carried up from the fjord mainly on the backs of four of the seven members of the expedition and the four Greenlanders who had been brought in from the coast

By July 20 the central room of the hut, 9 ft. by 14 ft. on the ground, had been built and equipped, and one of the store-rooms as well. On this date Mr. Clarence R. Kallquist, the aerologist, and Mr. P. C. Oscanyan, jr, the radio operator, took up their residence in the hut, already equipped with self-recording instruments—barograph, thermohygrograph, single-register anemometer, etc—and with the aerological equipment. Beginning on July 21, a daily pilot balloon has been sent up, and all the instruments regularly observed.

As later completed in early September, the station hut is represented in Fig. 1. It was designed and constructed very largely under the direction of Fred Herz, a member of the expedition who has for years been associated with Prof. J. E. Church, another member of the expedition, and long the director of the Mount Rose Snow Surveys of California. The design has grown out of the experience at the Mount Rose mountain station, though it has been modified to meet the extreme conditions in Greenland. Its form is that of a low flat dome banked with sod and rock in such fashion as to give the wind but slight hold upon it. The inner living room is insulated by store-rooms along

the sides which have outer walls of sod and rock, and sod walls largely cover the ends of the building as well. The side walls of the inner room are of extremely thick canvas heavily waterproofed, and the room is lined with balsam wool one inch in thickness and in part covered with canvas. The

room has a floor with balsam wool beneath it. The end walls and roof are constructed in much the same manner except that here additional board walls afford rigidity and additional insulation. The two windows at the ends are of plate glass and double, with air space between. Ample ventilation is supplied at both ends of the room and at the ends of the store-rooms.

The site for the station was chosen at the head of this great fjord in south-western Greenland because a long arm from the inland-ice pushes out nearly to the sea on the south side of the fjord, and it was thought that this arm (unique in Greenland) would condense the moisture arriving in the 'lows' making their way up Baffin Bay.

making their way up Baffin Bay. This judgment seems to have been confirmed by the experience of the past season, for during the months of July and August, rains were of almost daily occurrence at the Danish settlements on the west coast, though we enjoyed clear skies at

seldom calm enough for the purpose, and the temperature relationships aloft are at such times much less interesting than when the wind is blowing. Efforts will therefore be made to use kites carrying the light Fergusson meteorograph, of which the station is provided with three. The pilot

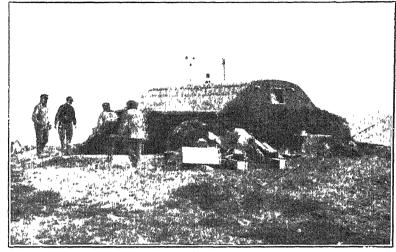

Fig 1 -Meteorological station near the margin of the inland-ice of Greenland.

balloon work will be continued once daily so far as practicable throughout the winter, making use of small lanterns during the dark period

The balloon studies thus far carried out already indicate that even in summer the Mount Evans station is almost entirely controlled by the inland-

ice circulatory system, the northern glacial anti-cyclone. With few exceptions the surface wind has been constantly from the easterly quadrants, and these extend upward to a height of about 1000 metres, where they are replaced by currents from the west which pass in over the ice. On Aug. 4 a very remarkable condition, and thus far unique in our experience, was discovered by the pilot balloon ascent A 73-minute run to 13,000 metres and 37,000 metres distance showed that the east wind, although weak at the surface, continued to the highest point reached. This was so remarkable that a second balloon was at once sent up and followed for 55 minutes, with the result that it checked almost exactly

with the first It will be interesting to learn what conditions were observed elsewhere on that day.

The delays at the beginning before reaching our base and the heavy labour of erecting the station on Mount Evans, left the expedition handicapped in its effort to advance over the inland-ice. Two reconnaissances had early been carried out and the inland-ice reached near the head of the great valley

FIG 2 —Mr Kallquist, the aerologist, following a balloon with the theodolite at the meteorological station on Mount Evans; Mr. Oscanyan is behind the instrument.

Mount Evans. The clearness of the atmosphere within this hinterland of south-west Greenland is best attested by the fact that the average run of our pilot balloons has been fifty minutes, and the average distance to which they have been followed has been thirty kilometres.

On Sept. 9, a free-rising captive balloon was sent up to a height of 1200 metres, but the days were

No. 3034, Vol. 120]

which extends the present fjord to the ice maigin In this district the inland-ice pushes out two tongues, which have been named the Russell and Leverett glaciers

It was not until Aug 8 that it was found possible to set out upon the expedition to the inland-ice, and arrangements had already been made with the Governor of Holstensborg for the Hvalrossen to come to our base at Camp Lloyd about Sept. 1 so as to bring three members of the expedition back to the coast in time to depart by steamer for Copenhagen. On setting out it was already clear that not more than a few days could be devoted to the ice itself. On Aug. 19 this little party, consisting of Belknap, Church, Herz, and the director, had reached the margin of the ice and set out upon its surface with stores and equipment loaded upon an Alaskan sled with harnesses for the four members of the party. At this time of the year the ice is without any snow cover whatever, and after leaving

pleted on Sept 3 and provisioned and fuelled for the winter A balloon inflating shelter large enough for captive balloons has also been constructed, and this greatly facilitates the aerological work such a location every structure must be made low, be built around with sods and boulders, and be heavily anchored if it is to withstand the winter A summer storm of hurricane force storms. occurred on July 21, the day after the central room and one store-room had been completed, and on this day the single-register anemometer recorded a wind velocity of 81 miles per hour This storm, which started in the south-east over the inland-ice and hauled into the south-west, preceded by about forty-eight hours, as we learned by our radio, the great storms along the whole Atlantic seaboard.

The powerful short-wave radio station on Mount Evans has taught us much concerning conditions of transmission within the district. Except during strong aurora displays, reception has been generally

good, and the New York Times news broadcasts have been received with great regularity. On the other hand, up to late September, transmission on shortwave by our 250 watt tube transmitter has been only rarely possible to distances beyond one thousand miles. Beginning late in September, contacts were established with the New York Times so that news despatches could be sent out. The station is equipped with a long-wave receiver, and its signals were heard distinctly at times when shortwave signals were blanketed out.

The ice-cap has been found to act apparently like an ocean, and the long waves come across it much better than they come to the station from other quarters. The weather announcements from

long-wave stations at Angmagssalik, on the east coast of Greenland, and from Reykjavik, Iceland, have been picked up regularly. It is hoped that amateurs and others will endeavour to communicate with our station during the winter. Its call is the Denmark-Greenland call with 1XL.

Because of the dog epidemic in north Greenland, it will be necessary for Bangsted to make up a team of dogs for the winter expedition from dogs available in the Holstensborg district. The difficulties of this expedition are fully realised, but Mr. Bangsted in mid-winter of 1926–1927 spent six weeks upon the surface of the inland ice to the eastward of Umanak, pushing his way a distance of eighty miles from the margin, turning back to a point twenty miles within the margin, and there carrying out meteorological observations for eighteen days before returning to Umanak. He will spend such time upon the ice and push his way to such a distance as conditions in the winter will make possible, starting out from the Mount Evans station and returning to it from the ice.

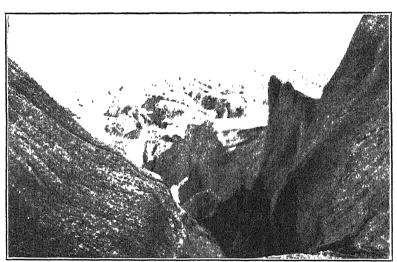

Fig. 3 —The rough surface of the inland-ice of Greenland over which the expedition had to advance

the immediate margin its surface was found to be so rough that the sled had to be relieved of most of its load and this carried forward in relays upon the shoulders. Without the crampons or climbingirons one could scarcely advance at all, and in the six days spent upon the ice an advance of less than eight miles was made. Pilot balloons were sent up on Aug. 23, and the party returned to its base after a 21 days' absence. Before turning back, an altitude upon the ice-surface of 2200 feet had been reached. On the return, depots of provisions and equipment were left behind for the use of a winter ice-cap party which will make the attempt to invade this region after the winter blizzards have filled the channels and packed the snow, and when the tundra surface separating Camp Lloyd from the ice margin is deep in snow and suitable for the use of dog-sleds. The winter party will consist of Mr. Helge Bangsted and Prof. J. E. Church, who have been making their preparations at Holstensborg.

The station on Mount Evans was finally com-

# Progress of Aeronautical Research in Great Britain.<sup>1</sup>

By H. E. Wimperis, Director of Scientific Research, Air Ministry.

N all countries alike the two most disquieting aspects of aviation to-day are the frequency of accidents to service aircraft and the necessity for subsidising nearly all civil aviation enterprises; it is therefore natural that research should concentrate upon the problem of increasing the safety of aircraft in addition to striving towards improving what is known as 'performance.'

There are obvious reasons why any craft moving in a three-dimensional medium should be safer than the older two-dimensional form of transport; that this is not yet the case is largely because all conventional types of aeroplane depend for their sustenance upon a horizontal speed of some 50-60 miles an hour, relative to the surrounding air. If this necessary speed be lost, the loss of control which almost invariably follows is highly dangerous unless the height be sufficient for the aircraft to recover speed If we can ensure that it will merely fall at a fairly steep gliding angle instead of starting to spin, then there is every prospect of 3 very considerable reduction in the number and . rious nature of aircraft accidents.

In England the problem has been attacked with vigour and a form of control has been evolved which, even at very large angles of incidence, has neither of the long-recognised defects of the conventional ailerons in stalled flight, namely, rapid weakening of power to bank the aeroplane, and the introduction of a yawing moment, which, if not countered by adequate rudder control, causes the aircraft to enter into a spin. This result has been achieved by the use of a slot in front of the aileron. The slot opening, which for convenience of design may or may not be quite zero in normal flight, increases as the aileron is depressed. Full scale tests have been carried out on a number of types of wing section and aircraft, and there would seem no doubt that the principle of the method can be made generally applicable. In the last few months a further simplification of the use of such a slot has been made by Mr. Handley Page: this is now under test and shows great promise. At the same time, the influence of the rudder-power on the control in stalled flight has been investigated. Although there is no evidence that safety in stalled flight can be achieved merely by increasing the rudder-power, research has indicated that the size of this control has a large influence on the rapidity with which a spin following a stall can be stopped.

It is common knowledge that some types of aircraft, when stalled, go normally into a spin and are not easily brought out, whilst other types of aircraft are difficult to spin. On what features of design does this difference depend? Can we, by a manipulation of the form and arrangement of wings, by disposal of the centre of gravity with respect to the centre of pressure or by some ar-

 $^{\rm 1}$  From a paper presented to the International Air Congress at Rome, October 1927

rangement of the control surfaces, ensure that a civil aircraft will never spin, and that a service aircraft will only have such degree of ability to spin as may be necessary for its particular duty? We know, for example, that a forward position of the centre of gravity will lessen in some degree the danger of an involuntary spin; we know that when positive stagger is reduced, the spinning properties of a biplane are more dangerous, but the picture is far from complete; though it may be said that the mechanism of a spin in undisturbed air is now generally understood.

A somewhat extreme example of an aircraft designed primarily to affect control at and beyond the stall, is the Pterodactyl, a tailless aeroplane, designed and constructed by Capt. G. T. R. Hill, with the financial assistance of the Air Ministry. This aircraft provides adequate control at low speeds by virtue of the fact that the fairly large floating control surfaces at the wing tips are fully effective at all probable angles of incidence of the mam planes. Successful full scale trials have been carried out with a lightly loaded tailless aeroplane, and it has been demonstrated that the aircraft has no tendency to autorotate. A tailless aircraft with higher wing loading is being built to the

order of the Air Ministry

It will be seen that much is being done to counteract the disadvantages arising from the natural limitation of the conventional fixed wing aircraft, namely, the dependence for sustenance upon a considerable forward speed. An alternative is the helicopter. We in Great Britain have from time to time looked not unhopefully along that road, but we have been compelled to turn away, always, indeed, with a little greater knowledge, but with a still greater respect for the magnitude of that attractive if elusive problem. But the task now seems not so hopeless as it once did. We have in England to-day a rotating wing aircraft having very attractive stability and controllability characteristics; I refer to the autogiro, the invention of Senor de la Cierva, belonging to the class we now call the 'Gyroplane.' This aircraft, by virtue of the hinging of the blades so that they can rise and fall as they rotate, escapes the instability which seemed at one time to be inevitably associated with rotating wing aircraft. Although not a helicopter, since it is not able to rise vertically from the ground, it is capable of almost vertical descent in a moderate wind It cannot yet be said that it will compete with the more conventional types of aircraft at high speeds, but for some purposes it would be advantageous to sacrifice high speeds in order to achieve safe landing in confined spaces. Research is proceeding, a number of gyroplanes are being built, and the nature of the forces involved in the flapping motion of a rotating wing are being investigated theoretically and by experiments in a wind tunnel. Moreover, the possession of a full scale rotating wing aircraft, the characteristics of which can be studied in actual flight, represents an exceedingly important advance towards the solution of the helicopter problem.

Of the other researches which are proceeding with the object of increasing the safety of aircraft, perhaps the work on wing flutter is of most general interest. It is well known that certain types of aircraft exhibit a dangerous wing flutter when diving at high speeds. We, in England, have not escaped this trouble, but happily we are within reach of an appreciation of the features of design Theoretical investigations which which cause it have been carried out at the National Physical Laboratory, and recent wind tunnel experiments at that establishment, have shown that it is possible to reproduce on a specially constructed model the various types of flutter indicated by theory. Research is proceeding, but already it is clear that the mass distribution and aerodynamic loading of the ailerons is a factor of prime importance scale experiments have also supplied very valuable data on the nature of wing flutter, and tribute must be paid to the skill and courage of the many pilots who willingly face the risk of diving aircraft at such speeds that flutter ensues, the knowledge so gamed is of the utmost value, but it is better to substitute work on the model scale for such dangerous tests wherever possible

On the subject of increasing aircraft 'performance,' one's thoughts turn naturally to the engine. One of the most amazing of modern engineering achievements is the production of a reliable power unit weighing little more than 1½ lb. per horsepower at ground level. For special purposes, such as for the recent Schneider Trophy competition, engines have been constructed weighing considerably less than 1 lb. per horsepower, but of course these engines are not yet suitable for general purposes

Engmes with gear-driven and with exhaust-driven superchargers have been built and have shown satisfactory power outputs at altitude, but our knowledge of how far the advantage of increased power is outweighed by the increase of weight, head resistance, fuel consumption, and of fire risk with the exhaust-driven type, is still incomplete.

There is another direction, however, in which attempts are being made to meet the need for operating in an atmosphere of variable pressure. It is well known that engines running at ground level, on ordinary aviation spirit, exhibit a tendency to detonate if the compression ratio exceeds about 5:1. At altitude the decreased air density and temperature allow higher compression ratios to be used without detonation, and for this reason most engines are designed to have a compression ratio larger than 5:1, detonation at low altitude being avoided by throttling the engine. tions such as these have led to a search for a suitable fuel which will stand a higher compression ratio without detonation. Tests on variable compression engines have shown that by adding some 20 per cent. of benzol, the compression ratio can safely be increased to 5.8:1, with a resulting decrease of

the weight per horsepower and a decreased fuel consumption, but for many reasons this method is unsatisfactory

It seems not unlikely that the best solution will be the addition to petrol of small quantities of 'dope,' the best known being a mixture of tetraethyl-lead and ethylene dibromide Indeed, it is not too much to say that the discovery of a 'dope' entirely suitable in its supply, use, and storage, would mark a new era in engine design. The decreased weight-power ratio and fuel consumption consequent upon the use of high compression ratios would seem only to be limited by the skill with which the designer could deal with the higher explosion pressures without undue increase of weight. It is clear that there is no lack of incentive to work in this direction. In England intensive research has been carried out at the Air Ministry Laboratory, at the National Physical Laboratory, and at Oxford on the physical and chemical nature of the phenomenon of detonation and on the effect of using 'doped' fuels. Much progress has lately been made; according to Prof. Callendar, working at the first-named establishment, detonation is due to the formation of organic peroxides which become concentrated in the nuclear drops during compression and ignite the drops simultaneously when the detonation temperature of the peroxide is reached. Although much has been done, it still remains to discover a 'dope' which will be entirely satisfactory in an engine, be non-poisonous, and will not deteriorate in storage. For civil aviation purposes, such a 'dope' would be invaluable, since the need for power at ground level at present conflicts with the necessity for using engines having a low compression ratio.

Every decrease of the weight-power ratio of aero engines inevitably focusses attention on the problem of effecting economy in fuel consumption. The average aero engine consumes its own weight of fuel in four or five hours, and it may well be argued that efforts to reduce the fuel consumption have not kept pace with the reduction of the weight of the engine itself. For long-range civil aviation, this problem is of particular importance. If, by the use of 'dopes' it were possible to use as high a compression ratio as, for example, 10:1, a substantial reduction of fuel consumption would be achieved. There is, however, another avenue of progress—the heavy oil engine. If the prospect of using compression ignition engines on heavierthan-air machines is still distant, the advantages to be derived therefrom are so important that the ultimate displacement of the petrol engine by the heavy oil engine can scarcely be doubted.

With regard to the design of the aircraft itself, it would seem that any signal advance must await the discovery of a new alloy or some new treatment of an existing metal or a new aerodynamic principle. There is room, however, for progress along less spectacular lines. Fundamental aerodynamical investigations are proceeding, and the later R A F. wing sections have been successfully designed in

accordance with the Kutta-Joukowski aerofoll theory. Preliminary experiments have been made on the removal of the boundary layer from the upper surface of an aerofoll by suction from points well forward in the section, it has been found that the maximum lift is considerably increased thereby.

Similar results could no doubt be obtained by the emission of air under pressure; but it will be appreciated that this is in reality the principle of the Handley Page slot, which, moreover, has the advantage of being independent of any pumping plant.

#### News and Views.

THE Council of the Physical Society has awarded the Duddell medal for 1927 to Dr. F. E Smith, Director of Scientific Research at the Admiralty. This medal is given annually for work in connexion with the development of scientific instruments or of materials used in their manufacture. Dr. Smith's work at the National Physical Laboratory on the development of electrical standards is too well known to require emphasis. He was trained at the Royal College of Science, 1895-1900, under the late Sir Arthur Rucker, entering the National Physical Laboratory in 1900. There he formed one of the band of pioneers who, under Sir Richard Glazebrook, did so much to raise the scientific work of the Institution to its present high level. His earliest work was concerned with modifications of the Wheatstone and Kelvin bridges for precise measurements of resistance, and the development of bridges for accurate platinum resistance thermometry. A classical piece of work followed on the current balance, by means of which it was found possible to evaluate a current of the nominal value of 1 ampere to within 1 part in 50,000. In the course of this work he developed the silver voltameter which bears his name and is generally accepted as the most trustworthy form of voltameter, in that there is no envelope between the anode and cathode. The successful development of the modern mercury-in-glass resistance standards is largely due to Dr. Smith's work. His specification for the Weston normal cadmium cell is the one generally followed. It is now no uncommon experience for a batch of twenty standard cells to be made commercially in which the E.M.F. given by the cells agrees to 1 part in 10,000. Dr. Smith was also responsible for the design of the Lorenz apparatus (the Viriamu Jones Memorial) installed at the National Physical Laboratory. He has also developed various magnetometers for the measurement of the magnetic intensity of the earth's field; one of his instruments now forms the standard for the measurement of the horizontal intensity at the Magnetic Observatory at Abinger. In 1920, Dr. Smith left the National Physical Laboratory to take up his present post at the Admiralty. He was president of the Physical Society for 1923-24. As one of the honorary secretaries of the British Association, his organising ability is being devoted in a striking manner to the advancement of science.

Mr. ROBERT MOND has been appointed a member of the research council of Imperial Chemical Industries, Ltd., to which reference was made in our issue of Dec. 10, p. 850. Mr. Mond has carried out notable research in pure and applied chemistry and has given particular attention to electrolytic problems. He was associated with his father, Dr. Ludwig Mond, in researches on the metallic carbonyls and the action of nitric oxide upon them. In other directions Mr. Mond has also contributed in a substantial way to scientific progress by his original work and personal influence, and he is as highly esteemed for his Egyptological explorations and studies as he is for his contributions to physical and chemical science. He is honorary secretary of the Davy-Faraday Laboratory of the Royal Institution and honorary treasurer of the Faraday Society; and many other societies and scientific organisations are indebted to him for generous support and encouragement.

Ir has long been known that the difference between good and poor pastures is not dependent alone upon the energy value of the herbage or the proximate food constituents—carbohydrate, protein and fat. The consequent investigations of mineral deficiencies, notably at the Rowett Research Institute, have already proved to be a well-directed inquiry. The discussions at the recent Imperial Agricultural Research Conference have made it abundantly clear that malnutration consequent upon mineral deficiencies in pastures is widespread through the Empire. From South Africa one hears that 'styfsiekte' in cattle arises on certain veld soils, the vegetation of which contains ss than the optimum requirements of phosphorus. The ruminant stock of the North Island of New Zealand have for some time been troubled with 'bush sickness,' a condition of anæmia and general emaciation which has now been shown by Aston to be correlated with iron deficiency. In the Bihar district of India low milk yield is consequential upon a low phosphorus content of soil and crops. The high mortality among sheep in the Falkland Islands has been found by Godden to be collateral with low lime and phosphorus percentages in the pastures. Similar evidence of malnutrition among Australian sheep is forthcoming. The pastoral industry of Australia contributes about 25 per cent. of the national income, a fact which makes the immediate investigation of mineral deficiency diseases imperative. These deficiency diseases are becoming more evident with the increasing population of the colonies, and the subdivision of the larger holdings. Stock migrated from one area to another in earlier days and so unconsciously secured adequate mineral supplies. The continuous maintenance of stock on the same area has now given rise to this new problem in nutrition, which is to receive full and immediate investigation largely through the cooperative efforts of the Empire Marketing Board, the Australian Council for Scientific and Industrial Research, the University of Adelaide, and the Rowett Research Institute.

At the thirty-second winter general meeting of the Institution of Water Engineers, held in the rooms of the Geological Society on Dec. 9, the following resolution was proposed by Capt. W. N. McClean, seconded by Mr. S. R. Raffety, and unanimously carried. "That there is urgent need of an organisation which will ensure a continuous record of the flow and storage of surface and underground water, and this Meeting desires the Council of the Institution to consider and report in what directions such investigation might be profitably developed." It is satisfactory to learn that water engineers are themselves dissatisfied with the present position in regard to the records of the flow and storage of surface and underground water. The subject is one of national importance; and for the adequate and equitable utilisation and development of the available water supplies, it is essential that statistical information should be generally available in regard to the distribution and amount of the supplies.

THE proposal in the Electricity Bill (1926) that all the electricity supply companies in Britain should supply alternating current energy at a standard frequency of 50 was the proposal which was most criticised. It was pointed out that in order to standardise the frequency it would be necessary to change over some of the largest supply systems in the country. The National Electricity Board, instructed by the Electricity Commissioners, is now supervising this change. The Electricity Department of the Glasgow Corporation is one of the first to change over. Glasgow, which generates at a frequency of 25 cycles per second, is included in the area covered by the central Scotland scheme. The problem presented by the change over was quickly solved by instructing the English Electric Company to build for the Dalmarnock Power Station a 50 cycle turbogenerator set which has an output of 25,000 kilowatts. This unit takes the place of one of the existing 25 cycle machines. All the other units in the station will gradually either be converted or replaced. Active steps are thus being taken to secure for Great Britain the great boon of an electric supply of standard frequency.

In connexion with the Associated Edison Illuminating Companies' Convention at Colorado Springs, a spectacular method of illumination was shown. The sunken garden of the Broadmoor Hotel was flooded with invisible ultra-violet rays from quartz tube mercury vapour lamps fitted with powerful reflectors. The light was filtered through special lenses made of Corning glass which obstructs all the visible light. It also prevents the band of short wave energy deleterious to the eyesight from passing through. As silvered glass reflectors absorb ultra-violet rays it was found necessary to make the reflectors of polished aluminium. The flowers, shrubbery, and evergreens were sprayed with chemicals which fluoresced under the ultra-violet rays. The chemicals used were zinc sulphide, eosin and

rhodamine. Each individual leaf, twig, or flower glowed in various colours. The water in the fountain in the centre of the garden was also treated with fluorescent chemicals so that it became brilliantly luminous when the rays fell on it.

LEPLAY HOUSE, 65 Belgrave Road, London, S.W.1, deserves wide publicity. Founded in 1920 on sociological principles laid down by Frédéric Le Play, principles that have been interpreted and enlarged by Patrick Geddes in studies associated with the Outlook Tower at Edinburgh, the House has worked steadily toward the better understanding of the complexity of city and regional life. Its work may well be styled the sociology of locality, the study of intricate and multifarious parts and functions as members one of another. From the beginning the main purpose has been to promote and assist discussion, study, and research in the field of sociology, and to apply the results to practical civic developments. This has been done by surveys undertaken through its own members or by voluntary and public organisations acting under its inspiration and advice. No one doubts to-day the wisdom of such surveys. The days of haphazard growth are past. Some scheme or plan of future development based on accurate knowledge of conditions is essential if a better future is to grow harmoniously out of an indifferent present. Local surveys cannot, however, be isolated from each other. Distance is the function, not of space, but time, and new means of transport, of thought no less than goods, are changing rapidly the geographic values of places. Regional surveys need themselves to be surveyed from a national viewpoint. This in practical politics means a central bureau capable and willing to advise and to co-ordinate. Leplay House fulfils these conditions, and the appeal by the Committee for Civic and Regional Institutes made on its behalf for personal and financial support should meet with ready response.

Previous to the founding of the Zeitschrift für Krystallographie und Mineralogie in 1877 by Prof. P von Groth, whose recent death at the age of eighty-five years we regret to announce, crystallographic papers in Germany had been published mainly in the Annalen der Physik und Chemie (Poggendorff), and mineralogical papers in the Neues Jahrbuch fur Mineralogie, Geologie, etc. The want of a journal devoted to crystallography was then beginning to be felt, but in order to gain a circulation it was at first necessary to add also mineralogy. When, in 1921, the editorship was taken over by Prof. P. Niggli, crystallography had made such rapid advances, due to the new X-ray methods of investigation, that a journal devoted to it entirely could be self-supporting, and the title was accordingly changed to Zeitschrift fur Kristallographie, as originally planned by Groth. In the current issue—the first part of vol. 66-Prof. Groth gives an interesting historical review and recounts the support he received from workers in many countries during his forty-four years of editorship.

As further marking the jubilee of the Zeitschrift für Kristallographie, some other changes are now intro-

duced with the view of making the journal still more international in character. On the wrapper the names of eighteen well-known workers (in twelve countries) are given as associate editors, the representatives in England being Sir William Bragg, Prof. W. L. Bragg, and Sir Henry Miers Of the fourteen papers contained in this issue, nine deal with the structure of crystals as determined by X-ray methods, and two of these are printed in English. There are also two separately-paged appendices giving connected reviews, rather than a disjointed series of abstracts, of special branches of the subject. Although the Zeitschrift is printed and published in Germany, the editor in chief, Prof Niggli, is Swiss, and an inspiring teacher in Zurich. Such international cooperation in science is a healthy sign and promises well for the future As further evidence of international goodwill in mineralogy, mention may here be made that, at the annual meeting of the German Mineralogical Society in Breslau last September, Sir Henry Miers and Dr. L. J. Spencer were elected honorary members, and that at the last meeting of the Mineralogical Society of America, Dr. Spencer was elected an honorary life fellow.

EXCAVATIONS at Ur were closed down prematurely last year on account of lack of funds at a moment when exceptionally important finds of jewels and other antiquities gave every promise that the expedition was on the eve of discoveries of the greatest interest. This promise has been amply fulfilled by the opening of the current season Excavations resumed at the same point have already brought to light a royal tomb of two chambers built of large unhewn blocks of limestone, with walls three feet thick. This is in itself remarkable in an area in which this material was entirely absent, and was, therefore, extremely costly. The tomb had unfortunately been rifled, and the royal chamber produced little; but the outer chember, in which the king's attendants had been buried, contained one body which had not been disturbed. With this were personal ornaments of gold and silver. A number of copper vessels had been crushed by the roof, but a silver vessel with fluted sides was recovered. Notwithstanding the disappointment of finding the tomb rifled, the discovery is of importance for the light it throws on royal burials in early Mesopotamia. An adjacent grave, however, in which the coffin was intact, has provided a rich treasure. Mr. C. L. Woolley, who describes the find in the Times of Dec. 16, considers that it must have been the grave of a member of the royal family, though not of a king. The name Mes-kalam-dug is inscribed on each of the gold vessels taken from the coffin. A great variety of articles in silver, copper, and goldpersonal ornaments, axe-heads, lance-points, saws, chisels, etc., as well as gold and silver vessels, was found. One of the most remarkable objects was a gold peruke which completely covered the head of the skeleton from the forehead to the nape of the neck. It is interesting to note that four lances with gold-mounted shafts had been placed, one at each corner of the grave.

No. 3034, Vol. 1201

In Germany, high pressure voltages exceeding 100 kilovolts have been used for the transmission of electric power over long distances for nearly twenty years. The cities of Berlin, Magdeburg, Leipzig, and Dresden are provided with electrical energy by means of an extensive 100 kilovolt network, which is supplied by the super-power stations situated in the lignite districts in Central Germany. Overhead lines also transmit at this pressure power obtained from waterfalls throughout the States of Baden and Württem-Dr. Cohn, in the October number of AEG Progress, published by the Allgemeine Elektricitats Gesellschaft of Berlin, describes and gives a map of the super tension networks erected and projected in Germany. The development of these networks, although retarded, was not interrupted by the War, and has been taking place very rapidly ever since. It is stated that if we have to consider economy, electric power can only be transmitted about 130 miles at 100 kilovolts. To transmit power economically from southern to central Germany, a distance of about 360 miles, would require a pressure of at least 220 kilovolts. Lattice girder poles are exclusively used for high pressure transmission in Germany. For 220 kilovolt lines the distance between the poles varies from 300 to 400 metres, but when the lines have to cross rivers and valleys much greater lengths of span are used. The Water Power Conference at Basel in 1926 recommended the linking up of the power systems in various countries, as this is to their mutual advantage. In the near future important developments in this direction are expected.

In 1924, Finland invited representatives of the States bordering on the Baltic Sea to a conference from which resulted the setting up of a Baltic Geodetic Commission to deal with geodetic matters in which co-operation between these States is of importance. The second conference was held in Stockholm in 1926, the countries which took part being Germany, Finland, Sweden, Denmark, Danzig, Esthonia, Lettland, Lithuania, and Poland. The annual contributions of member-States are 500 dollars for the first three and 250 for the remainder. The conferences are held annually, and the report of the 1926 meeting has just been issued. The matters dealt with included remeasurement of the base lines in the various countries by the same observers with the same instruments; the measurement of triangles overlapping two States by observers of each State, independently of each other; the longitude differences between the standard stations in the various States; and measurements of gravity. The Commission considered the enlargement of its scope to include magnetic surveying over the Baltic Sea and adjoining lands, but a decision on the matter was postponed until the 1927 conference.

An illustrated article by E. H. Wilcox contained in the Scientific American for December describes how in the United States large areas are protected from lightning strokes by a ring of high steel towers, the tops of which are connected by wires. The wires are provided with numerous steel points, which dissipate the ground charge induced by a lightning cloud. By continual point discharges the potential gradient between the cloud and the ground is kept below the value necessary for the occurrence of a lightning flash; the principle of the method is thus opposite to that of the ordinary lightning conductor, which is designed to offer an easy and safe path to the lightning discharge. The wires carrying the discharging points are all well grounded and connected electrically with the reservoir or other object which is to be protected. The method has been applied to great open reservoirs of petrol in California, where temporary over-production has necessitated this method of storage.

PROF HENRY J. SPOONER has an article in the Society of Industrial Engineers Bulletin (vol. 9, No. 9), on the progress of the movement for the reduction of noise. He discusses noise in the home, in the streets. rubber roadways, noise in the work-place, and the cost in human wastage and in depreciation of property. He complains that research bodies have so far done nothing or next to nothing with regard to the problem. With much of what the writer says everyone will be in agreement. The reduction of noise would be of very great value to the community, and there is little doubt that the noise made by some machines could and ought to be diminished. The scientific study. though of the effects of noise on individuals, whether that noise be in the form of street noises or of particular noise from machines, is not easy. Efforts are being made now by the Industrial Fatigue Research Board to collect data with regard to the effect of noisemaking machines in clerical work. So far there has been no evidence of more sick leave or of a higher labour turn-over in departments using noise-making machines than in other departments. The individual reactions to the noise are complicated. One question that arises is how Prof. Spooner has arrived at his calculation of £50,000,000 economic loss through the There are so many variables in effects of noise. calculating the effects of any economic factor that one would like to know whether the figure belongs to the domain of scientific fact or popular fiction.

APPARENTLY there are only a few more parts of that monumental work, "A Critical Revision of the Genus Eucalyptus," by J. H. Maiden, yet to be published, 68 parts having already been issued, so that students of the Australian flora are awaiting the completion of the book, and particularly the key to the species, with eager anticipation. The almost inevitable postponement of publication of the key until the whole work is finished, is one of the chief defects of a monograph of this type in which publication is continued over a period of years, the first part of the present work having been issued in 1903. The difficulties arising from this are enhanced by the fact that no comprehensive scheme of classification of the genus has appeared in Mr. Maiden's "Revision." No doubt this will be remedied in the last parts, but certainly the usefulness of the book up to the present has been greatly impaired by these omissions, unavoidable though they may be. It has been announced that the manuscript for the last parts was completed by Mr. Maiden before his death, so that these may be expected to round off the whole work. In addition

to much valuable information of the usual type found in monographs, there is a great deal of subsidiary matter (e.g. classification of barks, timbers, fossil records, enemies, ecological notes), often illustrated by copious figures. The economic aspect of the genus has been dealt with fully, while numerous references to other work on the timber, oils, gums, etc., are included. However, unless some arrangements have been made for the issue of special sets bound up differently from the normal, it seems that the morphological and additional information will remain scattered here and there throughout the latter parts of the book. Criticisms in detail are best left until the work is complete: it may be pointed out, however, that the late Mr Maiden collected an enormous amount of information together, and even as it stands the book is invaluable to anyone working on the flora of Australia

A SECOND International Conference on Bituminous Coal will be held at the Carnegie Institute of Technology in Pittsburgh, Pennsylvania, U.S.A., during the week commencing on Nov. 19, 1928. The first conference was held at the Carnegie Institute in November 1926, and was devoted to discussions of the better utilisation of bituminous coal. It was attended by 1700 persons, including delegates from thirteen different countries. No definite programme for the second conference has been made, but it is expected that the latest developments in obtaining substitutes for petrol from coal, power from coal, low and high temperature distillation processes, smokeless fuel, gasification of coal, utilisation of coal tar products, coal as a source for fertiliser, and coal in relation to the production of fixed nitrogen, will be discussed.

The British Journal of Actinotherapy for October (vol. 2, No. 7) contains an article by Prof. Birch-Hirschfeld, of Konigsberg, on the value of ultra-violet rays in ophthalmology, particularly in the treatment of ulcers of the cornea and conjunctiva. This journal, which is devoted to the medical and scientific aspects of ultra-violet rays, is now published at 17 Featherstone Buildings, W.C.1.

The Ministry of Health has issued new Regulations (Statutory Rules and Orders, 1927, No. 1004), to date from Jan. 1, 1928, revoking the Public Health (Pneumonia, Malaria, Dysentery, etc.) Regulations, 1919. Trench fever drops out, as it is apparently now an extinct disease. Although malaria remains notifiable, the new Regulations exempt from notification a case of malaria in which the disease has been induced in an institution for therapeutic purposes (e.g. the treatment of general paralysis). But such a case, if liable to relapses, must be notified at least four days before discharge to the medical officer of health of the district in which the patient proposes to reside.

The exhibition by Mr. Burchell and Mr. J. Reid Moir at the rooms of the Society of Antiquaries of finds of archæological interest from Sligo has led two correspondents to express their views in letters to the Editor. Mr. Henry Dewey, of the Geological

Survey and Museum, Jermyn Street, London, S W.1, states that he has seen the specimens and documentary evidence, and is of opinion that "certain features shown on the 'implements' could be formed only by human agency . . . a parallel as regards their form and technique can be found among the Levallois implements discovered at Northfleet, Kent" Mr. R. Vernon Favell, Penberth, St. Buryan, Cornwall, states that he was greatly impressed by the exhibit, and that "the implements and cores are undoubtedly of human workmanship in the Mousterian manner."

Mr. W. E. MILLER, writing from Avenue Rambert, Clarus, Switzerland, describes observations on four occasions recently of a third rainbow bow inside the primary bow, and asks for an explanation of the phenomenon The rambow appears to have been a supernumerary (German, sekundare) bow The optics of these bows is described in the third volume of the "Dictionary of Applied Physics," page 525, in Dr. Humphreys' "Physics of the Air," page 463; and in Pernter and Exner's "Meteorological Optics," 2nd edition, page 531 onwards. On page 594, Pernter and Exner give some notes as to the deductions about the size of the raindrops which can be drawn from the observation of these supernumerary rainbows may be of interest to recall that in Nature of Nov. 9, 1911, there is an account of an observation by Mr E Newbery of a number of brilliant rainbows

one time six rainbows were simultaneously visible, of which four seem to have been supernumerary bows. The colours of supernumerary bows appear usually to be green and violet, but that is not invariably the case. One of the supernumerary bows observed by Mr. Newbery was nearly white.

MESSRS Dulau and Co, Ltd., 32 Old Bond Street, W 1, have just circulated Catalogue No. 155 of some 400 new and second-hand books on entomology. It will be sent free upon application.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned · - A demonstrator in physical chemistry in the University of Leeds—The Registrar, The University, Leeds (Jan. 10). A head of the chemistry and industrial chemistry department of the Technical College, Cardiff - The Principal, Technical College, Cardiff (Jan. 21). Lecturers in the Massey Agricultural College, New Zealand, as follow. Inorganic chemistry and soilchemistry, botany and field husbandry, agricultural economics and book-keeping, veterinary science and animal husbandry, agricultural bacteriology, agricultural zoology-The High Commissioner for New Zealand, 415 Strand, W.C 2. A junior assistant chemist under the directorate of explosive research of the Research Department, Woolwich-The Chief Superintendent, Research Department, Woolwich, S.E 18.

#### Our Astronomical Column.

SKJELLERUP'S COMET.—A new orbit of this comet, differing considerably from that of Mr. H. E. Wood, has been computed by Mr. B. H. Dawson, of La Plata, and distributed by the I.A.U. Bureau. Copenhagen.

$$\begin{array}{cccc} \mathbf{T} & 1927 \; \mathrm{Dec.} \; 18 \cdot 200 \; \mathrm{U.T.} \\ & \omega & 20^{\circ} \; 58' \\ & \Omega & 78 \; 43 \\ & i & 82 \; 41 \end{array} \right\} \; 1927 \; 0 \\ \log q \; 9 \cdot 5092$$

EPHEMERIS FOR 0h.

The new orbit agrees better than Mr. Wood's with a telegram received by the Astronomer Royal from Mr. Chidambarier, assistant at Kodaikanal Observatory, stating that the comet was seen there (evidently in full daylight) about two diameters east of the sum on the morning of Dec. 15. It was then at its nearest to the earth, log  $\Delta$  being 9812.

The new orbit makes the comet brighter than the former one did, but much lower down, and better placed for observation before sunrise than after sunset, though it may perhaps be seen in both positions. The comet was observed at Hanover and Hamburg on Friday evening, Dec. 16, and had an appreciable tail.

JUPITER.—Mr. B. M. Peek and the Rev. T. E. R. Phillips discuss (B.A.A. Jour. for November) some recent observations of bright spots on Jupiter's north equatorial belt. The chief point of interest is that the rotation period of the spots was intermediate

between the equatorial rate  $(9^h 50^m)$  and the temperate rate  $(9^h 55^m)$ ; also the period appeared to increase during the series of observations, thus approximating more closely to the temperate rate. It is very rare to find spots showing these intermediate values. Mr. Phillips suggested that the increasing period might be due to their rising higher in the Jovian atmosphere so that their durinal circle became larger.

At the meeting of the Royal Astronomical Society on Dec. 9, Prof. Turner exhibited some beautiful photographs of Jupiter taken by Prof. Douglas in light of various wave-lengths. Some of these were arranged to give a stereoscopic effect, by combining exposures a few minutes apart.

THE LIGHT CURVE OF MIRA CETI -This wellknown variable has recently passed through maximum, so it is of interest to note the results of observations in the last few years. There is an article on it in L'Astronomie for November, giving the results of three observers, L. Jacchia at Udine, C Popovici at Galatz, and E. Loreta at Bolognia. Minimum, mag. 93, was passed on 1924, Sept. 26, and maximum, mag. 34, on 1925, Jan. 10, or 106 days later; there was a curious pause on the decline, in February 1925, when it remained for 16 days at mag. 4 (Observer, C. P.). The next maximum occurred on 1925, Dec. 5, according to E. L., but 6 days earlier according to L. J. Both gave the mag. as 3 1. The next was on 1926, Oct 24, according to E. L., 3 days earlier according to L. J. Both gave the magnitude as 3·1. The light-curves, as drawn, progress quite smoothly except in February 1925. The last two minima could not be observed, as the star was too near the sun. On the other hand, the maxima now occur with the star near opposition, so the conditions for observation are very good.

#### Research Items.

ANTHROPOMETRY IN CENTRAL AUSTRALIA —A first instalment of the results of the University of Adelaide Expedition to Central Australia at the beginning of 1927, which appears in Vol. I of the Transactions of the Royal Society of South Australia, gives a general introductory account of the expedition and its method of working, and deals more specifically with the results of the anthropometric observations by Dr. T D. Campbell and Mr. C S. Hackett. Two halts were made, one at Ross Waterhole, 40 miles northeast of Oodnadatta, and one at Stuart Town, Alice Springs. The natives observed were Arunta with a few Luritcha, numbering 57 in all, 44 male and 13 female, and with a few exceptions all were full blooded. In addition to the anthropometric measurements, a number of investigations were carried out, including a study of aboriginal songs, and the expedition was fortunate in obtaining a kinematograph film of a circumcision ceremony as well as other films of technological interest. A striking method of locomotion involved in an extreme case of platycnemia provided a film of exceptional interest The means of the anthropometric measurements given are: stature 1630 mm, head length 189.6 mm., head breadth 142 mm., nose height 52 l mm., and nose breadth 486 mm. Cephalic index 747, facial index 81·3, nasal index 93 mm It is to be noted that the head is slightly broader than that of other records. The larger size of the nose is probably due to the greater preponderance of males. Comparing these results with other records by various workers, it is now possible to give a generalised picture of the Australian as a dolichocephalic, platyrhine with pronounced supra-orbital ridges and protruding lips. in colour dark brown, with low to deep waves on the hair, which is occasionally curly but never frizzy.

SOME CHINESE FROGS AND TOADS.—Mr Karl Patterson Schmidt, in his "Notes on Chinese Amphibians" (Bull. Amer. Mus Nat. Hist., vol. 54, Art. 5, Oct. 1927), describes the Chinese amphibians in the American Museum of Natural History, most of which were collected by the third Asiatic Expedition. Amongst these are four new species and one subspecies—three Rana, one Bufo, and one Batrachuperus, which are described in detail. The distribution of the common toads of central China is interesting; a sub-species of Eufo bufo being common round about Shanghai and the east, Bufo bankorensis very abundant in the west, whilst in between both species occur. Notes on the food of Bufo bankorensis show that it eats beetles, ants, grasshoppers, millipedes, centipedes, earwigs, and spiders; also plant remains were found inside it, and even a small toad. Bufo raddei had fed entirely on beetles, and Kaloula borealis, as is apparently usual in the group to which it belongs, had eaten ants almost exclusively. Careful notes and descriptions are made of all the forms identified, and photographic illustrations given of six species.

Nematodes of Birds.—Eloise B. Cram (Bull. U.S. Nat. Mus., 140, pp. 465: 1927) has prepared an account of about 500 species of nematodes in approximately fifty genera of the sub-orders Strongylata, Ascandata, and Spirurata found in birds. Many of the descriptions are from obscure publications. and the author has done her best. often with inadequate data, to produce a critical account. Only seven new species are described. The main emphasis has been placed on the Spiruroidea, which may be regarded as primarily and

characteristically bird parasites. These have intermediate hosts which are eaten by birds, the water birds eat the entomostiacan intermediate host, and the insectivorous birds acquire the spirurid from The author directs attention to the observation of Seurat that infective third stage larvæ of spinureds in arthropods when eaten by hosts other than the final one, eg. by rodents, migrate into the tissues of such a host and again encyst as third stage larvæ Such an miected rodent would serve as a passive vector and would account for the infection of birds of prey. Keys are given to the orders, suborders, families, genera and species, which will greatly facilitate identification of these parasitic worms, and appended are a list of hosts with their respective odea and the Trichiurata are not dealt with in this memoir.

THE NATURE AND EVOLUTIONARY SIGNIFICANCE OF MUTATIONS —Considerable attention has been refocussed on the problems of evolution by this year's presidential address to the British Association, and the paper on mutations in the American Naturalist (vol. 61, Oct 1927) will be read with interest. Prof. Gates points out that while organic evolution is now generally accepted as a historical fact, there never has been greater difference of opinion concerning the causes of the vast diversification of forms of life we now know. The problem of specific diversity is certainly not a problem with a single solution, although many biologists still try to explain all specific differences and all phylogenies in terms of one evolutionary factor, or on one pet hypothesis. Prof Gates dismisses the Lamarckian factor as having so far no satisfactory experimental evidence, he is of opinion that the inclanic variations of Tephrosia bistortata obtained by feeding the larve on smoke contaminated foliage cannot be given a Lamarckian setting. These variations are in fact due to actual germinal changes induced in certain of the germ nuclei. In recent years our increased knowledge of the structure of gametes of organisms, and the way in which differences arise in the germ-plasm and are transmitted by inheritance, has thrown much light on problems connected with mutations. Mutants show visible gametic differences—differences in arrangement and structure of the chromosomes. These discrete changes in the germ-plasm are of many kinds, some 'spontaneous,' some connected with crossing, some induced by environmental factors. Of whatever kind, they must have played an important rôle in the production of species and varieties. In the tracing of phylogenies an increasing amount of importance is attached to parallel mutations and convergences, and the tendency of modern phylogenies is to deal less with divergences and more with parallelisms and convergences, a tendency shown in the recent conclusions of Bower on the phylogeny of the ferns.

CHIMERAS IN POTATOES.—Bud mutations in potatoes, involving changes in colour or shape of the tuber, are well known, but a 'kostroma' mutant from the Russian variety *Imperator* differs from the normal only in having more dissected leaves and corollas. As described by Miss T Asseyeva (*Jour. of Genetics*, vol. 19, No. 1), this mutant remains nearly constant when propagated from tubers, but occasional leaflets revert. Removal of the 'eyes' from a tuber leads to the regeneration of fresh buds which usually show reversion to the normal parent form. In this way

the 'kostroma' mutant was shown to be a chimera Similar experiments with several other potato varieties lead to the conclusion that many of them are pericipal chimeras in which the outer layer of the tuber differs in its genetical capacities from the inner ones. This may account for some of the phenomena of pollen sterility in potatoes, as well as for the fact that forms produced from seeds frequently have tubers different from the parent clone. It may also have an important bearing on the question of 'running out' in potato varieties. Several of the common varieties are indicated as chimeras, though they may also be hybrid in the ordinary sense. The author suggests that bud mutations are usually of a chimerical nature, but there is no indication as to how the potato chimeras may have arisen.

Forest and Prairie —At the last meeting of the National Academy of Sciences at Washington, Prof. Cowles, of the University of Chicago, discussed the probable fate of the great stretches of rolling grassland beginning in Illinois and stretching across Iowa and Minnesota into Kansas and Nebraska, if they had not been ploughed into corn and wheat lands A brief account of the paper has been issued by Science Service, of Washington Prof Cowles distinguished two types of prairies, edaphic and climatic. The former, occurring as interruptions in otherwise forested areas, are due to peculiar conditions of soil, soil water, soil chemistry or other soil conditions where they occur This type is by no means permanent, but exists as a stage in the development of some more stable type of vegetation trees that surround the edaphic prairie modify soil conditions along the border until they are able to creep over it and establish themselves on the grassland Climatic prairie is typified by the unbroken stretches of grassland in the west, and its existence is determined by general climatic conditions, regardless of local differences in soil It is a permanent type, to which all kinds of plant assemblies in the region gradually revert if left to themselves, for the climatic conditions under which it develops are unfavourable to tree growth. 'Tension line' prairies also, which occupy an intermediate position between edaphic and climatic prairie, will in the end become forest under a state of Nature

GEOGRAPHICAL FACTORS IN THE COTTON INDUSTRY. —The dependence of the cotton industry of Lancashire on imported raw material makes its location and growth at some distance from a seaport not a little remarkable, and especially was this the case in its early days, in the sixteenth and seventeenth centuries, when land transport was bad. In a paper in the Journal of the Textile Institute for November, Mr H. W. Ogden discusses the geographical basis of the industry. His paper is particularly valuable for the number of old and modern maps with which it is illustrated. He takes into account only the geographical factors, without denying that historical causes have also played their part. The cotton port was originally Chester, and it was not until the Dee lost its usefulness by silting that, early in the eighteenth century. Liverpool began to displace it. Mr. Ogden goes at length into the distribution of weaving and spinning in the cotton manufacturing area, and shows that the important geographical factors were the upland area to the east, with abundant rainfall, giving an even supply of soft water throughout the year. Soft water in abundance is required for all the processes of manufacture, while the application of steam power to the industry caused a further demand for it. Details are given of the distribution of rainfall.

OCEAN WEATHER.—A useful series of data is collected and tabulated from various sources by the Koninklijk Nederlandsch Meteorologisch Institut bearing on the weather of the Atlantic, Pacific, and Indian Oceans The pamphlet (Publication of the Institute, 107 B) giving the data for 1925 has now appeared. There is no map, but the ocean is divided into ten-degree squares from lat. 25° N. to 30° S. in the Atlantic, from lat. 10° N to 20° S. in the Indian, and from 30° N. to 30° S in the Pacific Ocean. For each month, in each square, is given the force and direction of the wind, pressure, temperature of the air, and water, cloud, and percentage of hours of ram. A few squares in the Pacific are blank, and the figures in some squares, especially in the Pacific and Indian Oceans, are based on few observations. Others in the northern Indian Ocean are the result of several hundred records. The publication is considerably interesting, especially after the data have been plotted on charts.

RIFT VALLEYS.—An important paper on fault troughs, both superficial and profound, appears in the Journal of Geology, p 577, 1927, from the pen of Stephen Taber. He reviews the evidence bearing on the origin of the greater features of this kind, such as the rift valleys of Africa and the Rhine, and concludes that they have not been formed by thrust faulting. Of the responsible factors he favours tension as the most important, and shows that normal faulting should be accompanied by an uptilting of the plateaux along the rims of the trough It is realised also that extrusion of lavas and increase of density of the material in depth—due in part to expulsion of gases and crystallisation—must be contributory causes in many places. There appears to be some confusion between oceanic deeps and rift valleys, but the author is wise in advocating a complete investigation of the Bartlett trough by the co-operation of geodesist, geologist, seismologist, and oceanographer.

PHOTO-ELASTICITY.—Volume 7 of Scientific Papers from the Institute of Physical and Chemical Research of Tokyo contains three papers by Mr Z. Tuzi on the properties and applications of a new material, 'phenolite, intended for photo-elastic research. It is made from phenol and formalin by the catalytic action of ammonia and is baked at 150° C. It is easily worked, takes a fine polish, is very transparent, and light yellow in colour. It breaks in tension at 300 kilograms per sq. cm., its extension being proportional to the load up to the breaking point. When examined in polarised light under stress, about 10 equal stress bands are visible before the breaking point is reached, so that it admits of a much more accurate estimate of stress than does celluloid. Its coefficient of volume expansion is 0 000564 and its heat conductivity 0 00044 at 35° C. Photographs of the stress bands are given for beams of both uniform and varying thickness when loaded and when heated to 140° C and plunged into cold water.

LIGHT QUANTA AND INTERFERENCE.—Some interference experiments with weak sources of light, which are described by A J. Dempster and H. F. Batho in the November issue of the *Physical Review*, show in a conclusive way that a single quantum of radiation has sufficient extent to produce fringes. The helium line at 4471 A was employed, as its decay constant is known from the experiments of Prof. Wien with positive rays, and its intensity was determined in each instance by comparison with the radiation from a black body. Using an echelon grating, the characteristic double order patterns which could be photographed showed that the quantum retained its

coherence after simultaneous passage through several steps, whilst with an air film between parallel plates, an even more stringent test could be imposed, which showed that a quantum follows the classical laws of reflection and transmission, and recombines afterwards with the difference in phase required by the wave theory of light

ETHER DRIFT.—The latest repetition of the Michelson-Morley experiment, which is described by K. K. Illingworth in a recent issue of the Physical Review (p. 692), has yielded a null result, no ether drift being recorded greater than one kilometre per second, the probable error of the measurements. An interferometer was used of the modified type in which one of the totally reflecting mirrors is interrupted by a small step of about one-twentieth the wave-length of green light, upon which the fringes are formed and viewed. The half-shade appearance of the line of dislocation gives an accurate means of detecting small differences in path, so that a careful untrained observer can notice a shift of less than a thousandth of a fringe. The experiments were performed in the California Institute of Technology at various times during the summer of 1927, and included runs made both under isothermal conditions and with slow progressive changes of temperature, the effect of which could be eliminated in the final analysis of the observations

A NOVEL ELECTRIC FURNACE.—A new form of electric furnace is described in the Chemiker-Zeitung of Nov. 9, which is suitable for heating quartz or porcelain combustion tubes to a temperature of 1300° C. It is mounted on rails in such a way that movements of ten to forty centimetres are possible in four directions. This enables one to remove the furnace from the hot tube and to keep it hot while the tube is cooling. The furnace is supplied by the firm Laboratoriumsbedarf Gesellschaft, Essen

THE CRYSTAL STRUCTURES OF MERCURIC AND MERCUROUS IODIDES.—An investigation of the crystal structures of the mercury includes carried out by M. L. Huggins and P. L. Magill, and published in the October number of the Journal of the American Chemical Society, confirms the previous results of other workers. Crystals of both compounds are tetragonal and the required data for the analysis were obtained from Laue and spectral photographs. In the case of mercuric 10dide, HgI<sub>2</sub>, each mercury atom is surrounded tetrahedrally by four iodine atoms each at a distance of 2.77 A., and each iodine atom by two equidistant mercury atoms. The molecules appear to be arranged in layers, and the shortest distance between two iodine atoms in different layers is 4.10 A. The crystals readily cleave parallel to the (001) faces and this is probably accounted for by the fact that the attractive forces between the layers are much weaker than those between the atoms in any one layer. Mercurous iodide, Hg<sub>2</sub>I<sub>2</sub>, is an aggregate of IHgHgI molecules, each mercury atom being surrounded by four iodine atoms and vice versa. The shortest interatomic distances are: Hg - Hg, 2.72 A.; I - I, 3.42 A., Hg-I (on same tetragonal axis), 2.75 A.

ALUMINO - SILICATES AND OXALATES. — Aluminosilicates are of considerable variety and of abundant occurrence in the mineral kingdom, and many views have been expressed as to their constitution. Recently, Prof. Walter Wahl, of Helsingfors, in a series of papers published in Finnish journals and summarised in the Zeutschrift fur Kristallographie (vol. 66), has worked out a complete analogy between these and the alumino-oxalates. He had found that certain alkali aluminium trioxalates can be split up into

optically-active enantiomorphous isomers fore becomes necessary to write a co-ordination tormula with a central sexavalent (co-ordination number of 6) aluminium atom surrounded by six (C2O4) groups, giving a complex tervalent amon In some of these complex compounds the central aluminium atom is quadrivalent (co-ordination number of 4). Replacing the oxalate groups by 'silicyl' (SiO $_3$ ) and 'disilicyl' (Si $_2$ O $_5$ ) groups, co-ordination formulæ on the same lines are written for a large number of minerals. For example, orthoclase is written shortly as  $[Al_2(S_1O_3)_2(S_1O_5)_2]K_2$  and leucite as  $[Al_2(S_1O_3)_4]K_2$ , these formulæ suggesting an explanation of the breaking down of orthoclase into leucite and silica at Polymensed formulæ for the a high temperature micas occupy almost a page of print. Silica also is not always quadrivalent in the silicates, as suggested by analogy with the fluosilicates  $[SIF_6]R'_2$ , and there may thus be isomorphous replacement of silica with co-ordination number of 6 by aluminium also with co-ordination number of 6 Such a replacement had indeed been suggested by P. A. von Bonsdorff in 1821, but this was acceptable only before the current views of valency had developed, and these it seems must now be modified.

THE 'ISOMERIC' CHLORIDES OF RUTHENIUM. The results of work carried out by J. L. Howe and described in the October issue of the Journal of the American Chemical Society, seem to dispose of two of the problems connected with the chemistry of ruthenium, namely, the apparent existence of two isomers in the K<sub>2</sub>RuCl<sub>5</sub> series and the valency of ruthenium in the blue compound formed when ruthenium solutions are treated with a strong reducing agent. It is shown that the series previously considered to be M<sub>2</sub>Ru<sup>ii</sup>Cl<sub>5</sub> is really M<sub>2</sub>Ru<sup>iv</sup>Cl<sub>5</sub>OH containing quadrivalent, instead of tervalent, ruthenium, and that the so-called 'aquo' series is actually an ordinary series of tervalent ruthenium crystallising as  $\rm M_2Ru^{m}Cl_5$  ,  $\rm H_2O.$ There are, therefore, no isomeric ruthenium chlorides, and since K<sub>2</sub>RuCl<sub>5</sub> does not exist, a possible coordination number of five can no longer be claimed for ruthenium. In all the above salts the co-ordination number is six Hydrated ruthenium oxide is usually considered to be  $\mathrm{Ru}_2\mathrm{O}_3$ .  $x\mathrm{H}_2\mathrm{O}$ , but is more probably  $\mathrm{RuO}_2$ .  $x\mathrm{H}_2\mathrm{O}$ , since in solution it always gives  $\mathrm{H}_2\mathrm{RuCl}_5\mathrm{OH}$ . When the latter substance is reduced by two units, it gives the blue solution referred to above, which, therefore, contains bivalent ruthenium, as Claus supposed.

Variation of Engine Power with Height.—The manner of variation of the power of an engine with height has been the subject of much discussion in certain scientific circles for some time. It is of fundamental importance in the reduction of aeroplane performance to a standard basis of comparison. Many investigations have been pursued to determine whether it is more accurate to regard the engine power at a definite rate of revolution as a function of the density only or of the pressure only. Recently Mr. Capon (R. and M. 1080, Aero. Research Committee. London: H.M. Stationery Office 4d. net) has suggested that the power is more precisely represented as a function of  $(pressure)^{2/3} \times (density)^{1/3}$ . In a memorandum (R. and M. 1099, Aero. Research Committee. London: H.M. Stationery Office 4d. net) entitled, "A Discussion of the Law of Variation of Engine Power with Height," Mr. Glauert reviews this whole subject and shows that the simple pressure law is undoubtedly better than the simple density law, but for greater refinement, Mr Capon's suggestion certainly gives a very close approximation to the

## A Recent Modification of the Species-Idea.1

By Dr. A B DROOGLEEVER FORTUYN.

N view of the necessity of naming every organism, and from the fact that such a name often must be corrected when new biological facts become known, it follows that taxonomic systems are always changing Even the species-idea, which is the basis of taxonomy, The question which group of organisms is changing has a right to be called a species has been answered in different manners in different times. It seems to me that the question is always answered in agreement with the development of biology in general

Lamarck and Darwin founded the species-idea upon organs and their changes as revealed by morphology and physiology Mendel was the first to discover a means of analysing the organism through other than morphological and physiological concepts He detected the now well-known hereditary units or genes, these being the more natural units than

organs.

Because genes represented a new principle in the analysis of the organism they also came to be used as a new basis for the species-idea. This was done by Hugo de Vries in his mutation-theory, in which the existing species-idea of Lamarck and Darwin was partly changed and partly consolidated. A species from the point of view of de Vries—and I believe I may say that this is the prevalent speciesidea at the present time—is a group of organisms possessing the same hereditary qualities, the same set of genes, and thought to be genetically pure recent years the work of Johannsen and others has given us more insight into the question of what really constitutes a group of organisms that is pure in respect to heredity. Johannsen has termed groups of genetically identical organisms pure lines and a mixture of them a population. Pure lines are not the species of Nature, though they can be isolated from the latter.

We cannot define a species as a group of organisms having the same genotype,2 for it is known that often the male and the female of one species differ in the number of their chromosomes and in the number of their genes. Thus our idea of species must be wide enough to include organisms with genetical differences, as Dr. Hagedoorn and his wife, Dr. Vorstheuvel la Brand, have so ably shown in their book, "The relative Value of the Processes causing Evolution,"

The Hague, Martinus Nuhoff, 1921.

The Hagedoorns urge us to remember that a species is a natural phenomenon and not a theoretical conception. Species, as found in Nature, are mixtures of genotypes, so if we follow Johannsen and term such a mixture of genotypes a population, a species is a population, but not every population is a species. In order to be a species the individuals of a group must interbreed. Groups of organisms unable to propagate with one another do not belong to the same species. Therefore a species is a mixture of genotypes freely interbreeding and containing some types of homozygotes as well as several types of heterozygotes or hybrids.

Just because there is free interpreeding the group as a whole will have more or less constant composition and features, the type of the species. The absence of complete constancy in the character of a species doubtless renders it sometimes difficult to define, but on the other hand, as we know that species in

Nature are changing and unstable, our definition must take this fact into consideration.

Independent of the work of the Hagedoorns such ideas are rising in the minds of several investigators to-day E S Goodrich, for example ("Living Organisms," Oxford, Clarendon Press, 1924, p 151), called a species "an assemblage of closely allied and interbreeding races, differing from each other by small factorial differences, and representing as a whole its present phase of evolution" The great plasticity of such a definition of the species is obvious

So far as I know, no one has worked out this new idea of inconstant and impure species more in detail than the Hagedoorns, who have done so with much success Although a species is inconstant and genetically impure (that is, composed of many genotypes and their hybrids), it always tends to become more constant and more pure because in the struggle for existence an elimination of ill-adapted genotypes takes place, and because new genotypes may only be introduced through rare cases of mutation or of crossing with other species Therefore in accordance with the Hagedoorns we may call a species "a population which is so situated and constituted that it tends automatically to reduce its variability.

Under domestication so-called varieties exist side by side with the species to which they belong, though in Nature this is not the case. Among the spairows, for example, we find now and then a white specimen; but these albinos propagate with gray spariows and return in their offspring to the species. According to the Hagedoorns varieties do not exist outside a species, but within it. They call a variety "those individuals together which differ in some marked way from the common type, when there is nothing in the circumstances which isolates these organisms and prevents them from crossing treely with typical ones.

If a species be composed of many genotypes, the addition of one new genotype will not much alter the species. Therefore even a mutation will not always obviously change a species, but mutation remains a source for new genes and consequently for new genotypes, so it remains in this way one of the origins of species. On the other hand, new species may arise, apart from mutation and hybridisation, by mere isolation.

If a continental peninsula be transformed into an island and some members of a species originally continental thus become isolated, then the mixture of genotypes represented by the individuals on the island may be different from that obtaining among the individuals remaining on the continent. Both mixtures will move towards their own equilibrium, and therefore so long as they are isolated the island and the continent will each have its own species. These species would have arisen suddenly and without adaptation. In this way the fact may be explained that islands like the Galapagos having similar climate and conditions but being isolated from one another by deep seas have each their own closely related species of many types of animals and plants, a fact which Darwin failed to explain.

This new species-idea is of importance because it shows that there is no reason for specific discrimination among the individuals of a group freely inter-breeding. Take, for example, the house-rat. Be it presumed that from Norway to Manchuria, through Europe and Asia, all house-rats are freely inter-

From the Department of Anatomy, Peking Umon Medical College, Peking, China. Substance of a communication read before the Anatomical and Anthropological Section of the China Medical Associa-tion in Peking, September 1926.
 Genotype here means type of a set of genes, not the type of a genus.

breeding. In that case they belong to one species, Mus decimanus of Mus norregions. There is no reason to call the rat of Manchura, even it differs troug the European rat, a sub-species (Epinips norvegions caraco) or even a different species (Mus caraco) as has been done. Variation is found everywhere, for the very reason that a species is a population of many genotypes. If one wants a pure genotype one will not find it in Nature, but one may isolate it from the natural stock by breeding the rats scientifically. Therefore in research work it is often advisable either to use the impure species as such or to work with material which has been artifically and thoroughly

purified, but not with an arbitrary impure portion of the whole impure species.

A taxonomic name represents a phenotype, although it always suggests a genotype. In how far it really represents a genotype may only be detected after scientific breeding. Whether it represents a species may only be decided after a careful study in Nature of the life of the individuals indicated by the name. For these reasons palæontological names can never be proved to indicate more than phenotypes

This new species-idea is also of significance in the field of anthropology, for if mankind as a whole be freely interbreeding, then biologically speaking, mankind is only one species. It is a species so much the more because it tends to reduce its own variability by the extinction of some minor races and by other means. Pure lines are absent in man, while

hybrids, on the other hand, are numerous, because even the children of a man with brown and a woman with blue eves must be called hybrids. The groups recognised by anthropology as races certainly are heterogeneous portions of a heterogeneous whole, and then true nature cannot be fully understood without a thorough genotypical analysis.

#### Hydrography of the South Atlantic

THE cruise of the ex-gumboat Meteor terminated at Wilhelmshaven at the end of May last, after traversing 67,535 sea miles and crossing the South

Atlantic thirteen times between Africa and the South American continent. This is the only survey of the physical and chemical conditions of an ocean on such an extensive scale.

The fourth and final report of the expedition 1 shows that the programme of work, drawn up by the late Dr Mertz, has been very completely carried out, in spite of difficulties incidental to work of this nature. When the results of the observations are worked up and finally published, they will form a considerable addition to our knowledge of physical oceanography, and in all probability fundamental principles will emerge having applications of practical value Whether this happens or not, scientific exploration of this nature is an effective way of 'showing the flag,' an exceptional experience for the naval officers employed, and sound training for apprentices and seamen

Since H M S Challenger was sent m 1872 on a voyage of exploration of the conditions and life within the oceans, Germany has added much to our knowledge through the expeditions of the Valdiviu, National, Planet. Deutschland, and now of the Metcor. After the voyage of the Challenger, interest in the physical conditions of the oceans centred mainly in the drift of warm Atlantic water towards the north-west seaboard of Europe Observations, mostly by the Scandinavians, led to the inference that this moved slowly towards the Norwegian coast, the drift being stronger in some years and weaker

m others, and that these fluctuations in strength of the drift ran hand in hand with fluctuations in general weather conditions and affected the fisheries, most of which are seasonal and sometimes tail. It is to be hoped that an investigation, on a scale commensurate with the German South Atlantic Expedition, may sometime be possible in the North Atlantic, and particularly in the area to the westward of France and Ireland. A wide field for inquiry still remains open.

The report deals mostly with the programme of work carried out rather than with the results obtained. Undulatory movements in the water layers below the surface were found by A. Defant, most marked at and below the thermocline. Similar

<sup>1</sup> "Die Deutsche Atlantische Expedition auf dem Meteor" IV Bericht. Zeit. des Gesells fur Erdkunde, Berlin, 1927, Nr 5/6.

undulations have been observed by Helland-Hansen (see NATURE, Jan 1, 1927, p. 18) in the North Atlantic A use and fall of both temperature and salinity was very marked at depths between 100 and 250 metres at a position shown by an anchor on the track chart (Fig. 1) where the depth was 4350 These undulations appeared to be composed of waves having a period of about 121 hours and of shorter waves with a period of  $2\frac{1}{4}$  hours, as a

#### Larch Canker in Britain.

THERE is probably no more striking example of the assistance which the botanist, and more especially the forest botanist, can render the forester than that afforded by the lustory of the larch canker in Britain. The introduction of the European species of larch (Larix europæa) in the eighteenth century was followed by plantings, for the time, on a considerable scale. The fact that, owing to the durability and value of the wood, all sizes from an early age (e.g. for sheep-net stakes) are utilisable, resulted in the species being planted without reference to the kinds of soil it required, or, as important, in the absence of any working knowledge of the necessary thinnings which the young plantations required. Old ideas and opinions, founded on premises which lack the necessary scientific study of facts upon the ground, are difficult to eradicate.

The appearance of the larch canker (Dasyscypha

calycina Fuckel) in Britain and the devastation caused by this fungus in larch woods led to a scare in the later years of the nineteenth century. In some cases woods were so seriously infested as to justify their removal en bloc. Many others which with the knowledge of the disease now available could have been left standing, the seriously attacked trees only being felled, were cut down Worse still, larch grown in mixture with Scots pine and spiuce were ruthlessly

cut out under the mistaken idea that the fungus infection would spread In other words, that most disastrous occurrence in forestry, a 'species scare,' took place. A much saner view of the position was taken during the early years of the present century. The disease was studied out in the woods, and with the fuller knowledge obtained, many owners ruefully recognised that some of their older standing woods had been reduced in value by 50 per cent. or more owing to the wholesale removal of the larch a score of years or so earlier

Two primary causes for the widespread attack to which the larch was subjected were established: the unsuitability to the species of many of the soils or localities in which it was planted, and the excessive density of the unthinned plantations Bothwereundoubtedly contributory causes to the universal spread of the disease. It was established at the same period, however, that infected trees did not necessarily succumb to the attack; and that a young plantation of a few years' standing in which a considerable portion of the trees were infested would not die. moval of the worst of the diseased trees should be carried out, the rest being left and kept under observation. There are instances where

such plantations have completely recovered A description of this fungus and suggestions for its control are discussed in a Leaflet (No. 16) recently issued by the Foiestry Commission. It is pointed out that the European larch is chiefly affected, the more recently introduced Japanese larch (Larry leptolepsis) being seldom attacked; on the other hand, the West American larch (Larry occidentalis) appears to suffer even more than the

Under methods of control, the author of the Leaflet lays down, quite correctly, the necessity of not planting larch upon unsuitable soils. The dictum applies equally to many species, but is especially necessary in cases where a serious disease has made its appearance in the country: since the planter not only risks losing his own plantation, but his mistake also leads to the infection of neighbouring ones. On the subject of spacing, the author perhaps follows unconsciously the present policy of the Forestry Commission and advocates, in order to reduce the possibilities of attack, wide spacing in the formation of the planta-tions. "Never less than four and a half feet, or on the better sites five and a half to six feet." opinion is widely held in Great Britain at the present But it appears to be based on two fallacies. First, owing to the fact that the correct mode of thinning larch was not understood as practised in the

No. 3034, Vol. 120]

past, the plantations became congested, damp, and airless, and bad attacks of canker tollowed. Secondly, the laich has always been raised in plantations from planted-out plants. Saving one or two instances only, no larch wood has originated from natural regeneration or from sown seed in Great Britain. The Leaflet in question, and many other writers, appear to assume that larch will never be raised in dense natural woods in Britain. It appears at least doubtful that this assumption is likely to prove justified. As the Leaflet shows, the life history of the fungus and the conditions it requires to thrive in are now available to all. Many of the mistakes of the past are thus avoidable Once the correct methods of thinning are applied, it is reasonable to surmise that it may be possible to raise larch in Britain as well as other species in dense young woods and thus produce a finer quality of tumber.

# Activities of Czechoslovak Engineers.

THE magnitude of engineering undertakings in Czechoslovakia is not generally realised. The publication of the "Almanac" of the seventh conference of Czechoslovak Engineers and Architects (a profusely illustrated quarto volume of 432 pages) directs attention to the achievements of its members. The greatest Czechoslovak engineering concern, the Škoda works at Pilsen, occupies an enormous area, and the history of its precursor, the firm of Laurin and Klement, shows what rapid strides have been made in the construction of engines and motors for various purposes.

In the conference proceedings three authors dwell upon the extension of the use of power alcohol, whilst other chemical engineers foreshadow the use of both old and new poison gases in future warfare

Sugar is an important item in their export trade, and an account is given of the latest practice at a number of well-known factories. The report from the Semerce Experimental Beet-growing Station also gives an idea of the progress made in improving both the crop and the sugar content of the beets.

Mladá Boleslav, in north-east Bohemia, where the conference met, is near the centre of the gem, glass, and textile industries. Reference is made to all these in the "Almanac," which lives descriptions of the garnet-cutting industry at Turnov, the glass-making at Jablonec, and the textile trade of Liberec (Reichenberg).

Another subject which received attention is long-distance telephony. The construction and equipment of stations for this work and the essentials for good transmission of speech by cable or radio were described, together with an account of the transmission stations of Prague, Brno, and Bratislava.

Technical education has not been neglected in Czechoslovakia, and the principals of a number of special schools indicated to the conference the lines upon which their work is carried on, and make mention of the good results that have accrued.

An interesting feature of the conference was that prominent industrialists and statesmen were invited to suggest in which directions they considered there was scope for improvement and further development in engineering activities and to indicate where engineers had neglected to make the necessary developments in the past. Several instructive replies are printed in the proceedings, and it may be added that they are applicable to other countries besides Czechoslovakia.

# University and Educational Intelligence.

Cambridge —Dr M Dixon, Emmanuel College, has been appointed University lecturer in biochemistry

Under the will of the Rev. J. H. Ellis a sum of about £65,000 will shortly pass to the University. The Council announces that it has given preliminary consideration to the possibility of finding from this and other sources means to provide for a substantial portion of the new University Library and for new lecture rooms for the literary faculties A detailed report will be made next term

Sn Humphry Rolleston will represent the University next May at the tercentenary celebration by the Royal College of Physicians of the publication of William Harvey's book, "De motu cordis."

London.—An ofter by the joint committee of the Paviors' Company and of the Institution of Municipal and County Engineers to establish a part-time chair of highway engineering in the University for post-graduate students has been accepted.

OXFORD.—Ceeil Graham Traquair Morison, reader in agricultural chemistry, has been elected to an official studentship at Christ Church.

John Carew Eccles, Rhodes Scholar from Melbourne, has been awarded the Francis Gotch Memorial Prize and has been elected to a junior research fellowship at Exeter College.

John Hulton Wolfenden, Proctor Travelling Fellow of 1924–5, has been appointed lecturer in chemistry at Exeter College

Stanley Carson, Fellow of New College, has been elected a member of the Committee of Geography.

New science laboratories at the City of London School were formally opened on Dec 20 with a reception by the chairman of the school committee (Mr\_Cecil F J. Jennings) and the headmaster (Rev. Dr Prebendary Chilton), followed by a conversazione to which 1500 guests were invited. The site of the school on the Victoria Embankment is probably as fine, and certainly as valuable, as that of any school in the kingdom. The penalty of eminence in this case is the difficulty of extension. The present alterations have been carried out at a cost of £22,000, and include four class rooms, a large lecture hall, a new diningroom, an armoury, and the remodelling and refurnishing of the whole of the top floor for the teaching of science All this has been accomplished without encroaching to any appreciable extent on the playground space. The new extensions were rendered necessary by recent movements in the direction of teaching science on a broader basis and to larger numbers of non-specialists. The school was one of the first to introduce natural science into its curriculum. This teaching was by 'block' lectures covering a wide range and taking in the whole school, but with very little opportunity for practical work. It has been the fashion of late to depreciate this kind of teaching; nevertheless, the fact remains that many old citizens who became famous in after life had their enthusiasm aroused and their imaginations stirred by these lectures. This, rightly or wrongly, was followed by a lectures. period of increasing specialisation for the comparative few and concurrent limitation of opportunity for the The new movement is towards a broadening of the basis for all. General science, including biology, will be taught on the classical side, physics-withchemistry on the modern side, while on the science side limited specialisation in physics, chemistry, and biology will be possible.

# Calendar of Discovery and Invention.

December 25, 1758.—Newton having stated the principles by which the orbit of a comet could be determined, Halley traced the paths of twenty-four comets which had appeared between 1337 and 1698 Finding three tracks closely resembling one another, he was led to the conclusion that the so-called three comets were but different appearances of the same comet at intervals of about 75 or 76 years Further investigation, in which he allowed for the retarding influence of Jupiter on the comet, led to the prediction of this comet's return. He knew he could not live to see it, but he wrote, "If it should return, according to our predictions, about the year 1758, impartial posterity will not refuse to acknowledge that this was first discovered by an Englishman " As the time for its reappearance drew near, its orbit was recalculated and the comet was recognised on Christmas Day, 1758

December 27, 1831. — Recommended by Prof. Henslow to Captain Fitzroy, who was about to set out in HMS Beagle to survey Patagonia, Terra del Fuego, Chile, Peru, and some of the Pacific Islands, Darwin, then twenty-two years of age, joined the expedition as naturalist, and the Beagle, after being driven back twice by gales, finally left Devonport on her famous voyage on Dec 27, 1831 The trip lasted nearly five years, the vessel reaching Falmouth

on Oct 2, 1836

December 28, 1814.—It was while serving as a government civil engineer in the Corps des Ponts et Chaussées that Fresnel, on Dec 28, 1814, wrote to a friend inquiring what was meant by the polarisation of light. The information obtained was quickly mastered, and from that time dates the beginning of his valuable studies in optics

December 28, 1895.—On a building, at 14 Boulevard des Capucines, Paris, is a tablet commemorating the first public display of a kinematograph film by the

Brothers Lumière on Dec. 28, 1895.

December 29, 1566.—Few men of science have been called upon to fight a duel, but Tycho Brahe's fight at Rostock must always remain of interest to astronomers Tycho's quarrel with his adversary, Manderupius Pasbergius, is said to have originated in a difference of opinion respecting their mathematical acquirements. The duel took place on the dark evening of Dec. 29, 1566, Tycho then being twenty years of age. In the fight Tycho lost his nose, but, as Brewster remarked, "it was fortunate for astronomy that his more valuable organs were defended by so faithful an outpost.

December 31, 1839.—Weld's "History of the Royal Society "contains some interesting notes on Herschelas great telescope, and includes." The Herschelan Telescope Song," the "Requiem of the Forty-feet Reflector at Slough," written by Sir John Herschel, "to be sung on the New Year's Eve, 1839-40, by Papa, Mama. Madame, and all the Little Bodies in the tube thereof assembled." Three of the verses ran: Three of the verses ran:

Full fifty years did he laugh at the storm, And the blast could not shake his majestic form; Now prone he lies, where he once stood high, And search'd the deep Heavens with his broad bright eye There are wonders no living wight hath seen, Which within this hollow have pictured been; Which mortal record can ne'er recall, And are known to Him only who makes them all. Here watched our father in wintry night, And his gaze hath-been fed with pre-Adamite light; While planets above him, in circular dance, Sent down on his toils a propitious glance.

# Societies and Academies.

LONDON.

Royal Society, Dec. 8 (continued from p. 902).— F. H. Constable Spectrophotometric observations on the growth of oxide films on iron, nickel, and copper The reflecting power of the metallic films increased considerably on activation, this explains the bright-ening of the oxidation colours consequent on the oxidation of the metal. The phenomenon was imitated by oxidising a cylinder of metallic copper divided into four portions, burnished, sandpapered, and two electrolytically deposited The brightness of the respective colour sequences were in the same order as the brightness of the metal surface on which they were produced. The colour sequence on copper showed strong reds and weak blues This is attributed to the strong specific reflection of red light by metallic copper. The sequence of nickel was remarkable for the absence of red colour, only browns being visible, while the dark blue was of remarkable intensity effect is attributed to the specific absorption of nickelous oxide The colours on iron are normal to blue, after which the absorption becomes so strong as to distort the sequence.

J W Lewis An experimental study of the motion of a viscous liquid contained between two coaxial cylinders. Mathematical laws deduced by G. I Taylor for the case when ratio of interspace (d) to radius  $(R_1)$  of the inner cylinder is small have been When the outer cylinder is fixed, the expression for the critical velocity at which the laminar motion gives place to vortex motion holds for values of the ratio d  $R_1$  as high as 0.71, and for liquids the coefficient of viscosity of which varies from 0.006 to 0.018 C.G.S. The determination of the critical speed can be used for the measurement of viscosities. When  $R_1\!=\!0\!\cdot\!26$  cm., and  $R_2\!=\!0.45$  cm., viscosities from  $0\!\cdot\!008$  to 0.012 C G S can be measured

with certainty to within 1 per cent

C E Inglis · Oscillations of a bridge caused by the passage of a locomotive. Mathematical methods are developed for predicting the state of oscillation set up when a given locomotive crosses a bridge at a specified speed. The author, as a member of a committee appointed in 1923 by the Department of Scientific and Industrial Research to investigate impact effects in railway bridges, had the results of practical experiment to point the way Analysis is applied in the first instance to a long-span bridge where the state of oscillation is not sufficiently violent to stimulate spring movement in the locomotive. A more comprehensive analysis, in which bridge damping and mertia effects of the moving load are taken into account, is applied to the case of an actual bridge of  $262\frac{1}{2}$  feet span. Laboratory experiments with a model bridge and locomotive were also described

G R. Goldsbrough · Tides in oceans on a rotating globe. A method is developed by which it is possible to calculate the forced tidal oscillations in an ocean, bounded by two meridians, on a rotating globe. When the ocean depth is proportional to the square of the cosme of the latitude, the determination of the semidiurnal tide is slightly simpler, and it is with this particular case that the paper is largely concerned. The method, in the case of the stated law of depth, permits of the determination of the critical depths at which synchronism with the semi-diurnal tide takes place. In an ocean bounded by two meridians 60° apart (which may be regarded as a representation of the Atlantic Ocean) the critical depth is not far from the mean depth of the Atlantic Ocean. The tides of that ocean may then be considered as arising from

E. C. S. approximate synchronism.

W F. Sheppard: The fit of a formula for discrepant observations. For testing whether a set of observations is consistent with a particular hypothesis, the accepted method is Pearson's ' $\chi^2$ ' method. The discrepancies between calculated and observed values being found in the usual way, the extent of agreement is summarised in a ratio P, which is, broadly speaking, the relative frequency of occurrence of similar or greater discrepancies in cases of the kind considered When the hypothesis involves unknown constants which have to be determined from the observations themselves, the formula is not exact. The important theorem is that, whatever (correct) method we use for finding the constants and thence deducing the discrepancies, we arrive always at the same value for P. This is the result of linear relations between sets of discrepancies found by different methods.

J. Taylor. On a photoelectric theory of sparking potentials The sparking potential is a function of potentials the photoelectric emissivity of the cathode for the radiations accompanying the neutralisation of the positive ions at the cathode surface. It is assumed that no ionisation by collision is produced by the positive ions in the gas. The validity of the theory is examined for the case of helium and good quanti-

tative agreement is obtained

C. G Darwin: Free motion in the wave mechanics Whereas previously the wave mechanics has mostly been applied to a study of stationary states, the present paper discusses its application to cases where there is a progress of events The following problems are solved: Free motion of an electron under no forces; motions of an electron in uniform electric and magnetic fields; motion of an electron in an atom; motion of an atom in a uniform magnetic field; Stern-

Gerlach effect; motion of the spinning electron A. Fowler. The spectrum of doubly ionised oxygen (O III). The paper includes a catalogue of more than 300 lines attributed to O III, of which about one-half have been classified by the author and others. As was expected, the spectrum is generally similar to that of N II, and the terms so far determined are in complete agreement with Hund's theory. The assigned term values are based upon a sequence of three singlet D terms. The deepest term is of the type  ${}^3P_0$ , and for this the value 444661 has been determined by adopting Bowen's suggestion that the well-known green lines,  $\lambda 5006$  8,  $\lambda 4958$  9, in the spectra of gaseous nebulæ are due to irregular combinations of deep terms of O III. The corresponding ionisation potential of O III is 54.88 volts.

H. Dingle: The spectrum of fluorine (F I). The spectrum F I has been investigated in the region  $\lambda$ 7600 -  $\lambda$ 8400, and the wave-lengths of 16 lines have been measured. The analysis of the spectrum previously made has been slightly modified and extended, and an approximate ionisation potential of 18 6 volts calculated. Relative term values of F 1, based on the two metastable states of the core, have been deduced

Lord Rayleigh. The line spectrum of mercury in absorption. Occurrence of the forbidden 'line \2270,  $1^{1}S_{0} - 1^{3}P_{2}$ . This line can be observed as a sharp absorption line in the unexcited vapour. The quantity of mercury required appears to be of the order 107 times as much as for the resonance line  $\lambda 2537$ 

Lord Rayleigh · Series of emission and absorption bands in the mercury spectrum. (1) The less refrangible group is situated between  $\lambda 3000$  and  $\lambda 2600$ and consists of 42 emission bands and 48 absorption bands. The emission bands are diffuse and symmetrical, without heads, and the initial spacing is 250 cm<sup>-1</sup> and point of convergence is near λ2537. The initial spacing of the absorption bands is 148 cm.-1 and the convergence point about  $\lambda 2645$  (2) The more refrangible group between \$2350 and \$2290 Under this we have (a) A series of emission bands, symmetrical, without heads, which merge into an apparently continuous spectrum ending exactly at the torbidden line  $\lambda 2270$ , spacing about 70 cm<sup>-1</sup>, (b) a series of four bands, in absorption, without heads, (c) a series of absorption bands, of finer spacing than (b) and in part superposed on the latter vergence point seems to be about λ2261 The spacing

of these bands is initially only 18 cm<sup>-1</sup>.
W. H. Taylor and J. West. The crystal structure of the chondrodite series Chondrodite, humite, and elmohumite have been examined by the rotating crystal method and by the ionisation spectrometer. Humite is based on a simple orthorhombic lattice, space group V<sup>h16</sup>, the unit cell containing four mole-Chondrodite and clinohumite are each based on a simple monoclinic lattice, space group  $C_{j,\delta}^{5}$ , the unit cell containing two molecules. The crystals bear a strong crystallographic resemblance to each other and to olivine, based on a hexagonal close-packed arrangement (somewhat expanded) of O atoms and OH groups, amongst which are distributed Mg and Si atoms, in such a way that whilst Mg atoms he within groups of 6 atoms (O or OH) each St atom is surrounded by 4 O atoms. The Mg<sub>2</sub>SiO<sub>1</sub> portion of each crystal possesses the olivine structure. All three structures may in effect be regarded as built up of alternate layers (parallel to the c face) of Mg(OH), and olivine The cementing layer of Mg(OH), has the same thickness in all, whereas the thickness of the olivine layer differs for each, the ratio of the thicknesses being that of the Mg<sub>2</sub>SiO<sub>4</sub> content of each molecule.

Physical Society, Nov. 25.-A E Knowler: On the measurement of the electrical resistance of porous The resistance of a material is measured materials independently of that at the surfaces in contact with it. The method is specially suited to the measurement of the resistance of ceramic, refractory, and building materials. Results show that the conductrivity of a building stone is nearly proportional to its moisture content. - P. K. Kichlu. Regularities in the spectrum of ionised neon. The theory of Hund is applied in tracing doublet terms and intercombinations between doublets and quartets. Almost all the lines between 2500 and 3800 have been accounted for, with a tew discrepancies -- Ezer Griffiths. A calorimeter for the determination of the heat developed by fruit. A differential arrangement is used, one container being filled with apples and the other with dummy apples of the same thermal capacity, made of thin-walled glass spheres filled with moistened glass wool. Resistance thermometers composed of 80 yards of mckel wire in glass tubes are disposed among the apples and the dummies. They are connected differentially to a slide wire, on which a difference of one thousandth of a degree causes a movement of the contact maker of 3 millimetres. The air circulation is controlled so as to maintain at will atmospheres containing from 2 to 10 per cent. of carbon dioxide around the apples The moisture content of the air before and after circulation is determined by a dew-point apparatus, and a correction applied for the heat absorbed in evaporating water from the apples At a temperature of 20° C., sound apples generate heat at the rate of about 0.012 calorie per second per kilogram of apples; or for an apple of average size (21 inches in diameter) the rate of heat generation per second is one and a half thousandth calories.

Geological Society, Nov. 30.—C. W Osman The granites of the Scilly Isles, and their relation to the Dartmoor granites. Assuming that the whole of the granites of Devon and Cornwall are due to the same cause, late adjustments of the post-Carboniferous revolution; it is shown, by comparing the two ends of the series, that the isostatic correction-sequence of intrusions is similar in both areas Previous to the intrusion of the granites the south-west of England had been subjected to three separate toldings, and the positions of the granite-laccolites are directly related to the intersection of the ridges of these folds (a) Post-Sılurıan, Caledonian folding ; (b) Post-Middle Coal-Measures, Malverman tolding, and (c) Post-Carboniferous, Armorican folding. The granite-magma crystallisation shrinkage-jointing, in regard to the production of pseudo-anticlines and synclines, is significant of direct roof-cooling influence The deeper into the laccolite the jointing is observed, the flatter the bed-joints become, as the roof-cooling influence is exhausted, until in the centre of the islands the bedding-joints are horizontal Petrological differences between the granites of Bodmin Moor and the Scilly Isles and the remainder of the south-western granites indicate a different source These two grainte-lac-colites were supplied from a great Caledonian direction-fault or series of faults parallel with, but some miles off, the north-western coast of Cornwall; only from such great faults could the allied Lundy Island granite have been intruded, all the other granitelaccolites being intruded from the Start-Lizard series of faults. The pre-granitic xenolithic inclusions in the Scilly granites indicate a great difference in age between the floor and the roof of this laccolite

#### Festivals and Survivals.

ELSEWHERE in this issue we publish the first of a series of brief notes on the calendar, which will appear from week to week in the coming year. These notes will deal with the principal fasts, feasts, and festivals of the Christian year, referring especially to the traditions, the customs, and the usages which are or have been associated with them. When possible, attention will be directed to similar observances in religions other than the Christian where these present analogies to, or serve to throw light upon, the origin and meaning of religious tradition. It is by the citation of such parallels that much in popular belief and custom, which those who in the past were curious in such matters thought merely quaint or inexplicable, has been shown to be a survival of a primitive mode of thought and a corresponding ritual. In his monumental works on early forms of religion, Sir James Frazer has interpreted the meaning of many of these periodic and seasonal observances, and he has interpreted them in such a way as to throw light on their significance in relation to the lowly as well as more highly organised beliefs. Throughout the "Golden Bough," in examples drawn from the beliefs and practices of Christian and pagan alike, there runs the central theme of the doctrine of atonement, of the sacrifice of a deity incarnate in man or animal. of the victim offered up for the salvation of the community, whether it be a community of worshippers or of subjects, and sometimes of both.

Although the more primitive peoples of to-day as we know them may be by no means so unsophisticated as they are held to be in popular belief, yet in the simpler societies the primal springs of action are more readily to be discerned. In the more complex civilisations of advanced races they are overlaid and obscured by tradition, convention, and sentiment. In all alike, however, from the lowest to the highest, in the ultimate analysis the fundamental urge is directed towards the preservation of the individual and the race. In some cases the two may conflict, as they did in the opposition of the spiritual and the material in the monasticism of the Middle Ages: in extremes both may be ignored. Given these fundamental motives in conjunction with the primitive animistic interpretation of Nature, on one side there arises from the magical ideas connected with the organs of reproduction and their function, an abhorrence of a contravention of sexual regulations in combination with a periodic unrestricted licence of orgiastic rites; on the other, many and various means are brought into operation.

especially at certain seasons of the year, to promote the fertility and prosperity of the stock or crops, and to ensure the preservation and increase of the food supply The sexual licence of a normally strict society finds its analogy in the sacrificial rite or ceremonial meal which, it has been found, at times and with some peoples, ignores the taboo of the sacred animal Nor is it enough thus to enhance actively the forces of Nature, the individual and the group must be protected from the influence, more often malign than benignant, of the spirits, whether they be conceived as of the deities or of the Hence the propitiatory rites, the funerary ceremonies, and the various means taken to drive away or ward off spirits and the ghosts of the departed. These dimly survive even to-day. All Hallow-e'en is the Feast of the Dead, we still carry the dead man from the house feet first that he may not return.

In a community as that of the British Isles, which for the greater part of its history has been predominantly dependent upon agriculture, it should not be unexpected to find customs which point to a survival of these primitive ideas. Many of the customs of the 'harvest home' are to the ordinary observer now meaningless, but when, for example, as the last load is brought in, the men are drenched with water by the women waiting for them, the rainfall which will bring fertility in the future is ensured. When in some remoter parts a few stalks of corn are still fastened together in something of the semblance of a human figure or 'dolly,' it recalls the time when the precious seed was preserved for the following season by being regarded as a material form of the deity, and invested with all his sanctity. If it were possible to attain a position of complete philosophical detachment, it would not be far-fetched to regard the mystic communion of those who partake of a ritual meal of the first fruits of the grain, which embodies the spirit of the corn, or of the sacrificial victim in the religious rites of some primitive tribe and of those who hold the extreme doctrines of the sacrament as one and the same. To-day in Italy a blend of paganism and Christianity sets up in a field after the harvest has been taken twelve little corn figures around a thirteenth, representing in the traditional form of the corn spirit our Lord and the Twelve Apostles.

The election of a King or Lord of Misrule on Twelfth Night goes back far beyond the Saturnalia, with which it is usually compared, to their common origin in the ritual unrestraint of some primitive fertility rite. In even more dramatic form the folk dance 'gathering peascods' ensures magically

a full crop by the simulation of gathering it, and the Durham sword dance perpetuates the slaughter of the king to secure in a younger successor the vigour of the community. The Abbots Bromley horned dance may date from an even remoter time when members of a hunting community wore, not ash branches, but antlers on their heads to represent the deer, thus securing the food supply by a ceremonial representation of their prey. The Witches' Sabbath, obviously a perverted fertility rite, also may go back beyond the agricultural to a pastoral stage with a six-instead of three-monthly division of the year at spring and autumn, as well as enshrine the memory of a ritual cannibalism not entirely due to a morbid popular imagination.

It is not surprising that in the earliest days of the Christian Church a rigid abstention from the rites of paganism was required of believers, an abstention they frequently failed to observe Civic duties under Roman rule or in a community largely Greek entailed performance of, or participation in, a ceremonial involving religious elements Further, in an eastern population of mixed races and religions, the desire to take part in a general merry-making is sometimes apt to overshadow differences of belief. The early Christians were forbidden even to join in the custom of an interchange of gifts on the Kalends of January; but how strong was the hold of the old gods is seen in the perpetuation of the Mother Goddess and the Veiled Artemis in the Madonna; the medieval devil still shows the cloven hoof of Pan and the horns of the woodland deities.

When the puritanical aloofness of the early Christians gave way in self-defence to a spirit of compromise, the Christian feasts and fasts were made to agree in time with those of paganism or of the old dispensation. The celebration of the birth of Christ was fixed at about the winter solstice, the time of the great feast of the god Mithra, while the Crucifixion and the Resurrection fell at the celebration of the Passover and the spring festival of other oriental religions. It was the duty of the high priest to fix the date of the Passover from observation of the moon's phases · the Church still fixes the date of Easter in relation to the same phenomenon. The coincidence of these festivals did not escape the notice of the ancients themselves, and the followers of Mithra accused the Christians of having copied their rites, while a like accusation was brought against them by the Christians It must also be remembered that, owing to their racial inheritance and their social environment, the early Christians did not differ essentially in mentality from their fellows. However far apart they stood from them

m form of observance and theological doctrine, their fundamental religious ideations had not yet diverged much from those of their contemporaries

Traces of this relationship can be seen in the theological discussions within the Church to quite a late date. Purely magical ideas abound in the writings of the Fathers and the lives of the Saints Much of medieval and still later belief—witness the doctrine of witchcraft—is essentially primitive Mathew Hopkins, the Essex witch finder, who swam a witch or weighed her against the Parish Bible, differs in method but not in kind from the South African witch doctor who 'smells out' a witch by 'throwing the bones' Witchcraft was not merely a popular superstition. Even in the seventeenth century, belief in the witch to many was a test of orthodoxy, while the doctrines of the Council of Trent contain elements which are of the purest animism, at least in form, however theological interpretation may now attempt to explain them away.

The reason for the persistence of a primitive mode of thought which we now look upon as alien to the true spirit of Christianity is not far to seek In the spread of Christianity, however strong the denunciation of paganism, a certain toleration and adaptation was the practice This was inevitable, especially in the later days of missionary effort, when a prince and all his people might be baptised en masse on one day. It was impossible that every individual, or even that any considerable number, had already been personally convinced of his or her theological error and instructed in Christian doctrine Consequently, in the remoter parts, such as Britain, Scandinavia, Central Europe, a mass of pagan beliefs and observances survived under the ægis of Christianity. Slowly and very gradually, as in succeeding ages an increasing number of individuals of stronger intellectual calibre have emancipated themselves from the trammels of tradition, ritual, and belief has been purged. But in remoter districts, in the Balkans, in Russia, among all the peasant populations of Europe, they linger to-day In the British Isles most of them have vanished, but here and there traces of a forgotten belief still remain, while of what is lost something has been recorded by gleaners of these survivals of an older faith.

The succession of racial migrations and invasions which the British Isles have witnessed has superimposed culture upon culture. These the archæologist, the ethnologist, and the folklorist seek to
recover and differentiate. For this purpose the
festivals of the calendar are one of the most fruitful sources. The ritual observances of a primitive
people being associated with their chief preoccupa-

tion, the conservation of the food supply and the propitiation of the deified forces of Nature, centre around certain crucial seasons of the year, seed time and harvest, the summer and winter solstice, and the spring and autumn equinox—Transformed and degraded, their meaning forgotten, they survive in association with certain days and seasons in the Christian calendar—So beneath our Christmas hes the Saxon—Yule—A saint's day may hide the festival of a Celtic goddess.

#### The Flow of Water.

  Pp. xii + 372. (London: Sir Isaac Pitman and Sons, Ltd, 1927) 10s. 6d. net.
- (4) Modern Waterworks Practice By F. Johnstone Taylor Pp. 272. (London . Ernest Benn, Ltd., 1927.) 18s net.

THE control of water is one of the oldest branches of civil engineering, and to-day problems connected with the flow of fluids are of first importance in connexion with many scientific and technical activities Like the engineers of ancient times, the modern engineer has to control the flow of water in canals and aqueducts; where they constructed small reservoirs, he constructs to-day reservoirs of very great capacity. ancients drew water from shallow wells by primitive means, the engineer to-day uses deep well powerdriven pumps to draw water from strata hundreds of feet below the surface of the earth. For thousands of years the power of flowing streams has been utilised to work simple machines, but to-day the rams that fall on the mountain areas are directed into channels that convey the water to machines developing tens of thousands of horse-power.

So important has a knowledge of the laws governing the control and flow of fluids become, that in the training of students of nearly all branches of engineering the subject of hydraulics, embracing the fundamental principles of hydrostatics, the flow and measurement of water and other fluids, the design of machines for the pumping of water and for the utilisation of water as a source of energy, form part of the curriculum. It is not surprising, therefore, that there is a growing body of literature dealing with particular branches of the subject, as well as with the fundamental principles of hydraulies. Of the four volumes before us, only the first can be said to meet a real need, the two books on hydraulies contain very little that cannot be found just as clearly and more logically developed in other books on the subject.

(1) Stream gauging has become a subject of real significance in the economic life of most countries. The United States, from which the first book comes, and the Dominion of Canada have for a number of years been engaged in a hydrographic survey of the water available in the natural streams, and very valuable data have been gathered as to the sources of power available, and the water available for irrigation, domestic, and manufacturing purposes. In Great Britain a good deal has been done, but in this country and in other parts of the British Empire much remains to be done, and this work, dealing with American experience, should be useful to students and to engineers concerned in the gathering and utilisation of data

Two preliminary chapters deal with the general principles of the flow of water in open channels in an elementary way, no attempt being made to justify usually accepted formulæ. In the third chapter, experimental curves (determined by Darcy and other workers) of distribution of velocity in the sections of open channels are considered; the shape of the velocity curve on a vertical section is fully discussed, and methods suggested for finding the mean velocity on a vertical section. Gauging stations and the methods of gauging streams and analysing the results are described in The defectiveness of the current meter in determining small velocities is rightly emphasised, and the student is warned of the care necessary to obtain reasonably accurate results from such instruments. The last chapter of the book deals with a subject not of great importance in Great Britain but of very great importance to Canada; the effects of ice on stream flow and on the form of the velocity curves for ice-covered streams become of very great importance when a stream is required for hydroelectric power production. An appendix is attached of fifty-two well-selected problems relating to the gauging of streams. The work forms a useful addition to the literature of an important engineering and economical subject.

(2) and (3) Both the volumes on hydraulics are written for the student That by Schoder and Dawson claims to have been written, however, "in the atmosphere of engineering activities." This volume contains matter that is found in other works on hydraulics, but, quite consistently with the real aim of the subject, it only deals with continuous flow, whether in machines or other No reference is made to the hydraulic appliances press or crane, or to reciprocating hydraulic en-The first three chapters deal gines and pumps The flow of fluids with hydrostatics and flotation through orifices is dealt with in a simple but somewhat empirical manner, there is a lack of logical development and authorities are not quoted. Useful data and references relative to submerged orifices and short tubes are, however, given

The general impression given by the book is that students in the United States approach technical subjects with insufficient mathematical preparation; otherwise it would scarcely be necessary to give detailed instruction as to how the value of  $v^2/2g$  can be obtained by means of a slide rule. The authors appear to be fearful of assuming that readers have an elementary knowledge of the fundamental principles of mechanics, and write a good deal on the flow of fluids before mentioning Bernoulli's theorem. On the other hand, the authors plunge into the use of the calculus immediately, in the chapter on flow over weirs, and use it to deduce the flow over a rectangular weir and a V notch in a manner which James Thomson and Prof. Perry years ago thought was entirely unjustifiable. It is an abuse of mathematics to integrate over an area in which the conditions do not even approximate to those assumed in the mathematical analysis. The remaining chapters dealing with flow in pipes and channels and with centrifugal pumps and turbines call for no particular comment. It is of interest to find a chapter dealing with flow of oil and gases in pipes. Revnolds's work and the criterion for similarity  $vd/\nu$  is referred to, but this is not developed very far.

The book by Lewitt bears much more the stamp of a work specially written with the examination in view, and the whole impression gathered from reading the book is that the least amount of critical study possible has been given to the subject. The only excuse, perhaps a laudable one, is that of dealing with as much as possible in a half-guinea book. As an example—a very elementary one—the usual formula  $v = \sqrt{2gH}$  for the velocity of flow through an orifice is given, and two proofs are offered without any reference whatever to the

assumptions made. The pressure and direction of motion at the section where the velocity is v is not mentioned, and there seems no escape from the unjustifiable assumption that the velocity v is the velocity through the plane of the orifice; the educational value of a critical study seems to be entirely lost. As another example of the author's unjustifiable assumptions likely to be harmful to students, reference might be made to p 304, on which is given the usual analysis of the formula of Poiseuille to determine the coefficient of viscosity It then follows that

$$\frac{mig}{v^2} = 8\left(\frac{dv}{v}\right)^{-1}$$

where m is the hydraulic mean depth of a tube and the other terms have their usual significance. Without further discussion he says, "this may be written"

$$\frac{mig}{v^2} = C \left(\frac{dv}{v}\right)^{"}$$

"where C and n are constants depending on whether the flow is stream line or turbulent." Such reasoning is entirely unjustifiable, as only by experiment is it, or can it be, known that

$$\int \left(\frac{vd}{v}\right) = \binom{vd}{v}^n$$

when the flow is turbulent.

So far as it goes the text is clear, and typical examples are worked out, but neither in order or treatment can it be said that the author adds to existing works on the subject. Following other writers, he includes a chapter on presses, cranes, etc. Unless a student knows already something of the constructional details of a single-power jigger, it is doubtful if he will gain much from the illustration on p. 342.

(4) The fourth volume, "Modern Waterworks Practice," deals very briefly with the fundamental subject matter of the second and third volumes. It naturally commences with "sources of supply." Reference is made to streams, lakes, and underground supplies, and the necessity for careful investigations before deciding upon the water available. The vexed question of compensating water is only briefly mentioned. Earthen, masonry, and reinforced concrete dams are briefly dealt with. The analysis for the buttressed dam may be right or wrong; from the reading of the text it is impossible to say, and the formulæ given must be taken on trust. The author states that the coefficient of discharge for a syphon spillway is from 0.60 to 0.65, but he gives no authority, and the statement must be taken with great reserve. The descriptions of the various types of plant found in connexion with modern waterworks are clear, though somewhat sketchy, and as a preliminary book for young engineers and students it will be valuable, but for purposes of design, other larger and more critical specialised books will need to be consulted.

# A Geography of the World.

Géographie universelle Pubhée sous la direction de P. Vidal de la Blache et L Gallois. Tome 1: Les Îles Britanniques. Par Prof. A. Demangeon. Pp. viii + 320 + 56 planches 80 francs.
 Tome 2: Belgique, Pays-Bas, Luxembourg. Par Prof A. Demangeon. Pp. iii + 250 + 40 planches 60 francs (Paris: Armand Colin, 1927.)

THIS work, of which the first two volumes have now been published, was planned some fifteen years ago, and was already in active preparation when the European War intervened. When work on it was resumed, the originator and editor, M. Vidal de la Blache, had died, but the project was carried through by M. L. Gallois on the lines that had been laid down. The facts of geography are not new, but the geographer can view them at a fresh angle, and this book is an excellent example of how the geographical outlook, with its selection and correlation of facts and linking of cause and effect, can illuminate the description of a country.

(1) Prof. A Demangeon, in his volume on the British Isles, has given the best account of the geography of this country that has yet appeared. It is not so full as some regional monographs, but it gains in being more vivid, and the picture of the whole is never dimmed by tedious detail. Not only is he comprehensive in his treatment and accurate in his facts, but also he writes with a clear understanding of the attributes and distinctions of the various parts of the country. We can recall nothing in English that is equally successful in portraying and explaining the scenery of Britain and the life of its people.

A book so packed with facts and venturing frequently on estimates of human and social characteristics might well lend itself to easy criticism. But the reverse is true. There is little that one who knows intimately most parts of the British Isles can find fault with. Prof. Demangeon's command of facts is equalled only by his balanced judgment. Some of his chapters on the landscape and its origin also show great descriptive power. We would commend particularly the chapters on

Scotland, with their intimate study of Edinburgh's traits and his long chapter on London, its origin, growth, and life.

One of the few omissions of any significance is an apparent neglect of the port of Immingham, perhaps because its statistics are generally combined with those of Grimsby Dundee has now no whalers left, and Leith is the only whaling port in Britain. Mention might be made of the part that the granite industry played in the fortunes of Aberdeen. Bibliographies are attached to each chapter. On the whole, they are good, even if a few entries might be replaced by more modern books and a few somewhat trivial books omitted. There is a full index of place names. The illustrations are well chosen and are of real value.

(2) The second volume, on Belgium and Holland, maintains the same high standard and is particularly interesting in its account of the struggle against the encroachment of the sea and the scheme now in progress for the partial reclamation of the Zuider Zee. The complete work in fifteen volumes is to cover the whole world.

R N. R. B.

# Agricultural Education and Research.

Ministry of Agriculture and Fisheries: Intelligence Department. Report on the Work of the Intelligence Department of the Ministry for the Two Years 1924-26. Pp. 86. (London: HM. Stationery Office, 1927.) 2s. 6d net.

IMMEDIATELY after the War there was manifested a great enthusiasm for research in nearly all the branches of science, and in agriculture, where the relation of pure science to the applied branches and to the practice of the field is a very close one, there was launched a number of comprehensive schemes both for the pursuit of knowledge and for its dissemination throughout the agricultural community. The time has now arrived when it is possible to view the good first fruits of some of these schemes and to say au revoir to others which have been found impracticable, or were born before their time.

It is eminently satisfactory to find that so much of the original planning has survived the stringent test of action and that the foundations and footings of a great and progressive agricultural service have been established. This service owes a very great deal to the ability and breadth of view of one man, and as it grows and produces its results, not only in Great Britain but also throughout the British Empire, the great work of Sir Daniel Hall will be

made manifest As chief scientific adviser to the Ministry of Agriculture it has been his business to select from the inchoate mass of suggestions, inferences, and wild-cat schemes and to build up a working plan which would cover the needs of fundamental research, agricultural education, and advisory work among farmers, and the terms of the report of the Intelligence Department of the Ministry of Agriculture before us make clear a measure of his success

Such work and such organisation have required the expenditure of very large sums of money, by far the greater part of which has come from the public purse, but, to take a single year as an example, it is reassuring to find that the £700,000 spent in 1925 on agricultural education and research is equivalent only to 0·3 per cent of the annual production of the land of England and Wales.

The research institutes, each with its own department of interest, make possible the carrying through of necessary fundamental work in the increase of knowledge and at the same time give the necessary agricultural bias to the scientific facts evolved. Ideally, they should pursue pure science, with a lively consciousness of the agricultural background which must colour their work in the public view. Actually, they vary very much in their regard for pure and applied science and in their appreciation of the fundamental and ad hoc problems presented to them

One of the great difficulties which has been encountered in the past few years has been the supply of men with two sides to their heads, and capable of appreciating at once both the scientific problems presented in pure research and the bearing which these must have upon practical agriculture. This difficulty has been greater, perhaps, in the recruitment of the advisory services than in the research institutes, but it has been encountered in both spheres, and it has often made difficult the maintenance of understanding and sympathy as between laboratory and field workers.

The universities so far have not been entirely successful in producing a supply of research workers who, in addition to possessing a wide view of their subject, are able to think in terms of action. The tendency to strict specialisation in research work is necessarily very great, but there would surely be a great advantage to the agricultural service in general if the young men coming from the universities were compelled to obtain actual field training in some department of an ordinary farm before being allowed to settle down into their allotted groove of work.

Students from Scotland and the north of England have a considerable advantage over the southerners, in that a very large number of them have had to work on the land in their early days, and this may perhaps account for the very large percentage of northerners in the research and advisory services. The provision of scholarships, rich enough to attract really able young men of all classes, and the construction of a sort of ladder by which a bright boy can climb from the village school to the greatest of our universities, via such places as farm institutes and agricultural colleges, has helped the supply of men, but there is still much to be done.

One of the greatest difficulties encountered in the agriculture of the past has been that of the exchange of ideas between experienced agriculturists and the dissemination of trustworthy information. It is almost proverbial that the link between the laboratory and the farmer is a very weak one, and it is therefore all the more satisfactory to find that the agricultural advisory service continues to grow both in numbers and in the good graces of the farmers themselves

The change in this department in the past twenty years is very remarkable. In 1907 there were scarcely any county organisers and only a few lecturers, and they were regarded with the utmost suspicion by the farmers of their districts A few outstanding characters earned for themselves reputations for wisdom and soundness, but it was done by force of personality rather than learning. To quote a well-known agricultural adviser addressing a meeting of his colleagues recently "Twenty years ago no self-respecting farmer would be seen speaking to an organiser, while now they seek you out in the market and, what is more, do what you tell them " There has been a great change of heart, and the present generation of farmers is anxious to learn, and is not convinced that the law of the grandfathers is immutable.

The organisation of the framework of the advisory system is almost complete over the country, and the supply of trustworthy information to farmers on almost every subject connected with their business is assured. It remains now for the advisers themselves and the farmers to take full advantage of the inquiring spirit of the age and of the opportunity which is offered. We, especially those of us who are farmers, have been apt to regard our own coasts as the limit of our concern and interest. This parochial view is shaken daily by the closer contacts in the market and in conclave with other parts of the British Empire, and it is

interesting to find that our home advisory service is being depleted of some of its best young men by the creation of attractive posts for them overseas An Empire Marketing Board, an Imperial Research Conference, a common pool of research workers and advisers—it seems that agricultural science progressive and well organised is about to take its proper place as one of the dominating influences in the development and progress of the Empire

CLEMENT HEIGHAM

#### Our Bookshelf.

Histoire des bois et forêts de Belgique: Des origines à la fin du régime autrichien Par le Comte Goblet d'Alviella. Tome 1 Pp. xvi + 490 + 18 planches. Tome 2 Pp xii + 350 + 16 planches Tome 3. Pp. ii + 140. (Paris Paul Lechevalier, Bruxelles: Maurice Lamertin, 1927) 3 vols. 100 francs.

A COMPLETE history of the forests of Belgium from the earliest times up to the end of the eighteenth century is given in these three volumes, which embody the results of much learned research The economic and social importance of the forests throughout the ages is the main subject of the work, but much light is also thrown on the natural history of the woodlands and on the gradual but late development of scientific sylviculture and forest management. Folk-lore, legislation, charters, archives, ancient MSS., classical writings, and modern books have all been laid under contribu-An agreeable feature of the work is the high quality of the full-page illustrations, which reproduce famous landscape pictures, maps, plans, and photographs

A great variety of information is scattered throughout the work. In every period much destruction of the original forests has taken place. The early natives and their Roman masters regarded the forests as mexhaustible, and ruthlessly plundered them for fuel and timber. Increasing population necessitated more agriculture for its support, and this was only to be obtained by encroachment on the land covered with trees. From the sixth century onwards, the civilising Benedictine monks, in their zeal for farming, were probably more destructive of woodland than the early pagans The forests that now exist in Belgium and France owe their preservation throughout the Middle Ages to the feudal lords, who loved the chase, and instituted severe game laws, depriving the peasants of their rights to fell timber and pasture their flocks in the forests. The sites of the ruined forests can often be recognised in the modern names of villages and communes. Ypres was so called on account of the elms (yppen in Flemish) which were numerous in the woodland where the town was first built In the years before the War, the country around Ypres was still noted for its numerous fine elms, which were survivors and descendants of the trees in the original virgin

Lectures on Dielectric Theory and Insulation. By Dr. J. B. Whitehead Pp vii+154 (London McGraw-Hill Publishing Co, Ltd., New York McGraw-Hill Book Co, Inc., 1927) 12s. 6d net

PROF. J. B WHITEHEAD, who is professor of electrical engineering at the Johns Hopkins University, has done much valuable research on insulating materials. During 1926–27, when he was an exchange professor in France, he gave a series of lectures on the properties of dielectrics and the phenomena which occur when high electric stress is applied to insulating materials. These lectures he now publishes in book form, and they will be very helpful to physicists and particularly to electrical engineers.

In the first lecture, Prof. Whitehead gives a brief and accurate account of the more important postulates which have been made in the classical theory of perfect dielectrics. Most of the material in the following seven lectures is taken from recent papers on physics and electrical engineering. The results, however, have been co-ordinated and they are presented in a way which will be appreciated by those engaged in research. The author points out the most promising directions for further research. The last chapter is devoted to researches on the properties of composite insulating materials when subjected to very high electric stresses. In this chapter he incorporates many of his own researches on these materials when subjected to high alternating stresses. In conclusion, a very complete bibliography of the subject has been given. It is arranged under six general headings, and we have found it useful.

Bacterial Vaccines and their Position in Therapeutics. By Prof. Leonard S. Dudgeon. (Modern Medical Monographs, edited by Prof. Hugh Maclean.) Pp. vii + 87. (London. Constable and Co., Ltd., 1927.) 7s. 6d. net.

This book is essentially a record of the personal opinions of the author after an extensive experience of twenty years on the preparation and use of prophylactic and therapeutic vaccines in different diseases. Rabies and vaccinia are included, although not strictly bacterial, but prophylaxis by means of diphtheria toxin, and Dick's scarlatina toxin, are omitted Very few diseases are included for which the author has not himself used vaccines. Much sound and valuable advice is given about the kind of case in which vaccines should be avoided or only given with great caution. For the rest, the advice, if rather conventional and based on almost purely empirical clinical grounds, is backed by experience and free from the uncritical and dangerous optimism of many treatises on the subject. Prof. Dudgeon is adverse to the treatment of acute general infections by vaccines. The more recent advances in the theory of prophylactic vaccines and bacterial antigens are unnoticed, and in this the author consistently adheres to his policy of dealing only with what he himself has tried for a long period. No reasons are given in support of the use of therapeutic vaccines beyond the author's personal belief in their efficacy, and no new experimental evidence is adduced.

Hippokrates · eine Auslese seiner Gedanken über den gesunden und kranken Menschen und über die Heilkunst Sinngemass verdeutscht und gemeinverstandlich erlautert von Dr. Arnold Sack Pp. vi +87. (Berlin. Julius Springer, 1927) 3 60 gold marks.

In this booklet, Dr Arnold Sack, of Heidelberg, has made a judicious selection of the most important passages in the works of Hippocrates and rendered them into readable German—The passages selected include the oath, and extracts among others from the law, the surgery, the epidemics, airs, waters, and places, the prognostics, dentition of infants. nature of man, care of health, and numerous aphorisms

In the postscript, Dr. Sack maintains that though nothing definite is known about the life of Hippocrates, it is certain that he was not a mythical personage, but really did exist, as is shown by allusions to him in Plato's dialogues, and not only practised medicine but also wrote medical works. It was not until many centuries after his time that commentators of the Hippocratic works appeared in Alexandria, Athens, and Rome, the most prominent of whom were Galen and Herophilus No critic has yet been able to determine with certainty which of these works was written by Hippocrates himself and which by his pupils. It is, therefore, not surprising that some of the passages selected by Dr. Sack are from works regarded by other commentators as spurious

Finlayson's Clinical Manual for the Study of Medical Cases. The fourth edition Edited by Dr. Carl H. Browning, Dr. E. P. Catheart, and Dr. Leonard Findlay; revised and augmented throughout by various contributors. Pp. xvi + 815 + 4 plates. (London. G. Bell and Sons, Ltd, 1926) 18s. net

Many physicians and students will greet with pleasure the publication, after an interval of thirtyfive years, of a new edition of "Finlayson's Clinical Manual" The great progress made in all branches of medicine, and particularly in diagnostic methods, has necessitated the complete revision of some parts of the book and the inclusion of much that is entirely new, but the general plan of the original has been retained, and there has been no departure from the principles of medical training indicated by the late Dr. Finlayson. The student is still taught the prime importance of observation at the bedside, first and mainly with his eyes, next with the hands, and last and least with the ears Laboratory methods, however, are not neglected. The technique of reactions which come only within the sphere of the bio-chemist is naturally omitted, but full details are given concerning investigations of general value, including recently evolved tests such as that of van den Bergh. The manual contains useful tables and a very complete index, and there is no doubt that this edition will be as popular as were its predecessors.

#### Letters to the Editor.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

#### The 'Palæolithic Implements' from Sligo.

WE have read the reply of Messrs. Reid Moir and Burchell, published in NATURE of Nov. 26, to our letter on the above subject. We note that we or our observations are old-fashioned, unwise, faulty, mistaken, abortive, dogmatic, and so forth; but we find little or no serious attempt to meet the main points of our criticisms, and we are so "unscientific" as to

hold that detraction is not argument.

Messrs. Reid Moir and Burchell specified three sites as sources of their 'implements.' They admit by implication that we identified two of these; for they make no effort to question any of our statements regarding them The third, they suggest, we "failed to observe" This is not the case; and their suggestion, based as it is upon an ambiguity of topographical nomenclature, is scarcely ingenuous. The squareheaded promontory of carboniferous limestone, south of Drumcliff Bay, comprises the townlands of Upper and Lower Rosses. In some of the older maps only the north-western angle of the promontory is called Rosses Point: but in current modern usage this name has been extended far beyond that narrow application, to which Messrs. Reid Moir and Burchell now wish to confine it. The village, church, post-office, hotels, etc., of Rosses Point all lie along the south coast of the promontory, one to two nules distant from the northwestern angle. Those unacquainted with the district can verify this by reference to any recent map, such as the six- or one-inch Ordnance, Bartholomew's quarter-inch, the Admiralty Chart, etc. Knowing this, and assuming that Mr. Burchell also knew it—as we think he must have done—we covered with our survey the "western or seaward side" of the whole promontory, including the north-western angle; with the results stated in our first letter. We have there already mentioned the only features, along the strip of coast in question, to which the term 'rock-shelter,' fallen-in or not, could by any stretch of imagination be applied; or to which Mr. Burchell's ambiguous indications could in reason be referred.

At this north-western angle, where we now learn definitely that Mr. Burchell's 'rock-shelter' is situated, we found only an ordinary storm-beach, composed of angular blocks derived from the rocks around it; and limited, as to its dimensions, by the nature of the ground, the character of the rocks, and the manner of their erosion. As there can now be no doubt that this is what Mr. Burchell claims to be a fallen-in rock-shelter, it becomes necessary to de-

scribe it with some particularity.

The beds of limestone referred to dip at a low angle towards the north-west. At the spot where the 'rock-shelter' is situated three beds are present. The *upper*, evidently the 'roof' of the 'rock-shelter,' is formed of a very cherty, much jointed grey limestone, and is about 2 feet thick. The *middle*, which is about 4 feet thick, consists of more thinly bedded grey limestone, almost devoid of chert. The *lower*, the 'floor' of the 'shelter,' is a more massive and compact limestone, brownish on the surface, quite devoid of chert, and easily distinguished from the other two.

The middle bed yields to marine erosion a little

more rapidly than either of the others. In consequence, undercutting of the upper bed is continually in progress; but, owing to its strong jointing, blocks fall away from it before there is any marked overhang. For this reason it is impossible that it could ever have formed a roof capable of giving shelter. The erosion of the middle bed exposes the lower bed, and from this latter rather large blocks, sometimes as much as three or four feet in length, become detached from time to time, and are cast up to a higher level by the winter waves. The erosion of the three beds thus advances, to all intents and purposes, concurrently.

The resulting storm-beach covers the whole area of the alleged 'rock-shelter'; and its dimensions agree with those of the 'shelter,' as given by Mr Burchell. But of the blocks which compose it, only about one-third come from the cherty upper bed (the 'roof') the other two-thirds come mainly from the lower bed (the 'floor'), having been cast up by the waves to a height several feet above their original position, so that they overhe some of the smaller debris.

The middle bed breaks up more readily into small pieces, with angular fractures. Many of these fragments are so recently broken that they have not yet been rolled by the waves, though some of them display chipped edges, produced by marine action. Stormwaves have free access to this material, as is shown by the copious admixture of recent marine shells associated with it—some of the bivalves being so fresh that they still retain their ligament. This mixture of stones and shells lies around and beneath the larger blocks; and it is from this material that Mr. Burchell's 'implements' have been selected.

The suggestion that this mass of rock debris could have formed the roof and contents of a Palæolithic rock-shelter would have appeared to us so ludicrous, had it so much as occurred to us, that we should have dismissed it forthwith. Since the publication of Messrs. Moir and Burchell's most recent letter, definitely indicating this spot as the site of their rock-shelter, two of us have revisited the place and reexamined it with care. Their report confirms us in our former conclusion—that it presents nothing more than a typical storm-beach, similar to those that are to be seen on Coney Island and at other places in the

neighbourhood.

After this second, more thorough examination, we are now able to say that in spite of Mr. Burchell's depredations it would still be possible to select, from among these fragments, specimens presenting a very passable resemblance to implements. There would be no difficulty also in finding among them shapeless lumps of stone which the most sanguine could never mistake for artificial products. If these two groups were laid out at a short distance apart, we might, with no very great expenditure of time and trouble, fill in the space between them with a complete senation of forms, gradually approximating from the one to the other. Even without the advantage of seeing Mr. Burchell's carefully chosen specimens, we can well believe that they look very convincing on the table of the Society of Antiquaries: but we suspect that they would be less impressive if they were lying where the last storms left them, mingled with these countless intermediate forms and with modern seashells.

Mr. Burchell's "Raised Beach of powdered shells" can be readily seen in the earthy bank just behind his 'rock-shelter,' though his reason for calling it 'Early Neolithic' is less obvious. It is a mere upward extension of the recent beach, and is likewise due to storm action, probably within the last century or two. The lighter fragments have been

projected by spray and wind farther than the heavier ones—that is the only difference which this upper edge of the beach presents in contrast to the lower part. The shells are of species now common in the bay, including Solen siliqua (predominating), Venus gallina, Cardium edule, Donax vittatus, Mytilus edulis, Ostica edulis, they occur in the same relative proportion from the highest point of the so-called 'raised beach' down to the lowest point of the present heach.

By quoting in support of their case a reference from the Geological Survey Memoir to a raised beach at Carney, Messrs. Moir and Burchell show themselves to be unaware that the study of Irish raised beaches has progressed within the forty years which have elapsed since that memoir was published. The Carney 'raised beach' is wrongly so described; it consists of shelly deposits, due either to recent storm action or to human agency. Similar shelly beds are frequent along the Irish west coast, as in Counties Mayo, Galway, and Clare. Those of human origin date, some from the famine year (1847), some earlier, some later. The well-known 25-ft. beach of Northern Ireland, so conspicuous in the north-east, drops to sea-level and merges with the present beach in Co Wicklow in the east, and Co. Sligo in the west, as is well shown in Wright's "Quaternary Ice Age," p. 422, Fig. 151. We repeat: No raised beach is known within this area.

If they had realised it, we were doing Messrs Moir and Burchell a service in pointing out their error in this matter. For, under the conditions prevailing on this spot, a Neolithic raised beach overlying a Palæolithic rock-shelter, such as Mr. Burchell describes, would be damning evidence against his We invite a consideration of what it would claims. (1) A rock-shelter formed by marine action in strongly jointed and bedded limestone, on very exposed ground, with (2) Mousterian implements on its floor; (3) heavy glacial erosion of the district; (4) submergence, until a beach was deposited above its roof; (5) emergence, until its floor was a few feet above ordinary high-water mark, (6) recent constal erosion, postulating more rapid crosion during the two preceding phases; and (7) after all these vicissitudes, the rock-shelter still surviving, save for blocks fallen from the roof, and still retaining exposed on its floor "more than 100 unrolled flakes and flake implements made of limestone"! (The italics are ours.)

Messrs. Reid Moir and Burchell complain that we prejudged the authenticity of the material removed to London without having examined it. If they will refer to our previous letter they will see that we were careful to avoid doing this. They also charge us with a desire to maintain at all costs a preconceived theory of the absence of Palæolithic remains from Ireland. Personalities of this kind possess neither interest nor importance, and are best ignored: but we may permit ourselves to say that here also they make a statement contrary to fact. We are ready to welcome any discovery of Palæolithic man in Ireland, by whomsoever made. We visited Rosses Point with perfectly open minds. Had we found that the sites agreed with Mr. Burchell's description, we should naturally have endeavoured to follow up our inspection of the ground with an examination of his collection. But the geological evidence proved so destructive that we considered that no useful purpose would be served by a journey to London, until the difficulties presented by the nature of the sites had been cleared This, we repeat, Messrs. Moir and Burchell have made no serious effort to do: accordingly our case rests where it did.

Much more might be said on other points that have

been raised in this correspondence: but we do not propose to trespass further on the hospitable columns of Nature, unless some new statement of fact be made, which in our opinion calls for notice. Just as a sentence removed from its context can convey a surprisingly false impression, so the Sligo 'palæoliths,' brought to notice by Messrs. Roid Moir and Burchell, cannot be fairly and fully judged without a competent study of the sites that yielded them.

Dublin, Dec. 5.

# Thermodynamics, Wave-theory, and the Compton Effect.

Prof. A. H. Compton's own explanation of the remarkable phenomenon discovered by him is well known and is set out very clearly in his recent book on "X-rays and Electrons." Briefly, it is that radiation is of a corpuscular nature, that the momentum of the impinging quantum detaches the electron from the atom and causes it to recoil, while the deviated quantum loses energy in the process and degrades in frequency. This view of the Compton effect, like Einstein's explanation of the emission of photoelectrons, approaches the relations between matter and radiation from a point of view so divergent from that of the familiar concepts of Maxwellian electrodynamics, that it is scarcely possible to understand how this conception of radiation is physically reconcilable with the familiar explanations of interference and diffraction phenomena.

As is well known, there is an addition to the X-ray scattering of degraded frequency, an unmodified secondary radiation the existence of which has been explained by Prof Compton as due to the whole group of electrons in the atom scattering conjointly. To this view, the objection might be raised that if one electron acting alone can scatter a quantum, and also all the Z electrons in the atom acting together, then why do we not observe scattering by two, three, or more electrons acting together at a time, with their corresponding fractional Compton shifts in wavelength? To the alternative explanation of the un-modified scattering given by Profs. Compton and Jauncey that it represents the scattering by an electron which the impinging quantum is unable to detach from the atom, the equally pertinent query may be asked, then why is the intensity of this type of radiation proportional to  $Z^2$  and not to Z?

In addition to these objections to Prof. Compton's explanations of his own discovery, there is another of a very fundamental nature which was also urged by me when, by invitation, I spoke at the British Association meeting at Toronto in August 1924, on the problems of the scattering of radiation. Maxwell's theory of light not only explains the classical phenomena of interference and diffraction, but also, when taken in conjunction with the principles of thermodynamics, affords a very complete explanation of the phenomena of the scattering of ordinary light in gases, liquids, and crystals under the widest range of physical conditions. This has been fully demonstrated by me and my associates in a series of experimental and theoretical researches during the last six years. Is it conceivable, then, that Maxwell's theory and thermodynamics taken together would fail in the closely alhed field of X-ray research? Urging this point of view, I referred at the Toronto meeting to the beautifully simple explanation which the classical wave-theory and thermodynamics together give of the X-ray diffraction haloes in liquids.

During the current year I have returned to this subject, and in a series of memoirs which are being published in the Indian Journal of Physics, have developed a general theory of X-ray diffraction and scattering in which theimodynamics, the classical wave-principles and modern views of atomic structure are brought together and shown to afford a simple and intelligible explanation, not only of Prof. Compton's own discovery, but also of the crucial experiments of Bothe and Geiger, and of Compton and Simon, which at first sight seem so destructive of the classical wave-ideas. It is not possible in the columns of Nature to afford more than the briefest indication of the line of thought followed in these memoirs

The facts of temperature radiation from solids and fluids compel us to assume that the thermal agitation of bodies excites not only the atoms but also the electrons contained in them. Starting from this premise, it is shown on Maxwellian wave-principles

that we must have two types of secondary X-radiation, one of intensity proportional to Z² which corresponds to the normal or stationary state of the atom, and the other proportional to Z produced by the thermal fluctuations of the internal structure of the atom. The former is a stationary or diffraction effect, and the latter is of a highly fluctuating type, the intensity of which has no fixed values at any time or place and the laws of which can only be formulated as statistical relationships. This type of scattering is identifiable with the Compton effect, and the observed variations of the latter with direction of observation, atomic weight of scattering atoms and wave-length of X-rays, and the observed fluctuations with respect to time and direction, are all satisfactorily explained.

In addition to these, the theory indicates that as the Compton effect is essentially a thermodynamic phenomenon involving degradation of energy, it should show a marked dependence on temperature. Experiments to verify this are in progress at

Calcutta, but there are already sufficient indications in the literature of X-ray scattering and absorption and their variations with temperature to indicate that the success of the experiments is a foregone conclusion. The results of the experimental work will also be published in the *Indian Journal of Physics*.

# The Magnetic Properties of Single Crystals of Nickel.

Last year Dr. Honda and the present writers published a paper dealing with the magnetic properties of single crystals of iron (Nature, 117, 753; 1926). The present paper contains the result of the similar investigations on nickel. In order to obtain large crystals of nickel, a strained bar of electrolytic nickel melted in vacuo was continuously heated at 1300° C. for several days, but the result was the formation of twinning crystals of several millimetres in length and no further growth took place. In the second trial, molten metal was cooled from the bottom of the crucible containing it by slowly lowering the vessel out of an electric furnace; in this way we were able

to prepare large crystals of nickel, 7 cm. in length and 2.3 cm. in diameter.

From these crystals three oblate ellipsoids, the flat planes of which coincided respectively with three principal planes (100), (110), and (111), were prepared. The major axes of the ellipsoids were about 20 mm, and the minor axes 0 6 mm. The processes of sawing and filing were always done by hand very carefully so as to avoid the least distortion of the crystal.

The results of the measurement of the magnetisation in the direction of the principal axes of the crystal are shown in Fig. 1. As is seen in the figure, the magnetisation curves in the directions of the tetragonal, digonal, and trigonal axes are almost straight, and coincide with each other up to an intensity of magnetisation of 205. Above this intensity the magnetisation varies for the different axes of the crystal, the trigonal, digonal, and tetragonal axes showing a decreasing order of magnetisability. This is just the reverse of the case of iron crystal. The saturation intensity of magnetisation is 503, which is

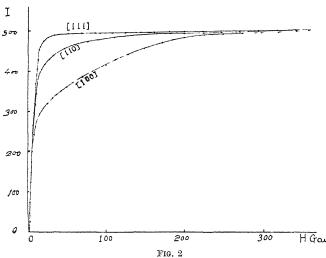

higher by 5 per cent. than the value 478 obtained by P. Weiss, and lower by 1 per cent. than the value 509 determined by E. Gumlich.

In plane (100), both parallel and perpendicular components of magnetisation in a constant field vary with a period of 90°. For the parallel component, the direction of the digonal axis has the maximum magnetisation, and that of the tetragonal axis the minimum magnetisation; but for the perpendicular component, the magnetisation vanishes in the direction of the tetragonal and digonal axes and attains a maximum or minimum between them. When the intensity of the magnetic field increases, the amplitude of these periodic changes increases, attains a maximum, and afterwards gradually decreases. The above periodic change coincides qualitatively with the case of iron crystal, when the direction of its principal axis is supposed to be rotated by 45°; this difference may be expected from that of the lattices in (100) plane for iron and nickel crystals.

In plane (110), two components of magnetisation vary with a period of 180°. For the parallel component, the principal and secondary minima take place respectively in the directions of the tetragonal and digonal axes, and the maximum in the direction of the trigonal axis.

In plane (111), the two components of magnetisation

vary with a period of 60°. The amplitude of these periodic changes is very small, not exceeding 4, which is only 4 per cent, of the maximum amplitude in the plane (110). In a weak field, the parallel component of magnetisation in the direction of the side of the equilateral triangle forming the space-lattice is a minimum, and that in the direction of the bisectors of the vertical angle of the triangle is a maximum; but in a stronger field the opposite is the case. These relations coincide qualitatively with the case of the (111) plane in the iron crystal when the direction of the principal axis is rotated through 30°.

The magnetic expansion-field curves for the directions of tetragonal, trigonal, and digonal axes are shown in Fig. 2. In the case of the longitudinal effect, magnetic contraction is observable for all fields, while in the case of the transverse effect, magnetic expansion is always observable. In both cases tetragonal, digonal, and trigonal axes are in the descending order for magnetic expansion or contraction; thus the order is just the reverse of the magnetisability.

# New Methods of Electrically Maintaining Mechanical Oscillations.

In the article on radio-frequency measurements in Glazebrock's "Dictionary of Applied Physics" (vol. 2, p. 635), Dye states that "quite powerful longitudinal vibrations in steel bars can be produced by acting on them with currents of the resonating frequency." From conversation with Dr. Dye, I gather that this refers to some otherwise unpublished work in which the oscillations are maintained by electric, that is, electrostatic, forces derived from an oscillating valve set and a polarising battery.

Experiments made by me on audio-frequency oscillations of metal rods under electric forces from a valve show that these vibrations can be obtained of great intensity with surprising readiness. The metal bar (of cast steel, mild steel, or brass) is clamped at its centre, and one plane end is placed close to the plane surface of a massive block of metal. This block and the bar are connected one to each side of the condenser of the valve maintained circuit,

a polarising battery being inserted in one of these leads. Tuning is carried out at first by comparing the note emitted by the bar when struck endwise with that heard in the ear-piece of a reed telephone, to which no leads need be attached, since the stray magnetic field from the induction coil in the valve set makes it give out a note of the frequency of the set. The final tuning may be made in this way by beats, or by beats between the forced oscillations of the bar and its natural oscillations evoked by impact.

A bar of the same material of half the length will vibrate without the polarising battery if the condenser

m the maintaining valve set be cut down to a quarter of its former capacity. The fine tuning in this case is by beats between the natural note of the bar and a faint note emitted by the induction coil of the set. This note is due to the unpolarised vibration of the structure of the coil set up by the main oscillating current. Rods and tubes of electrically non-conducting material could doubtless be caused to oscillate in both these ways, that is, by polarised or unpolarised electromagnetic forces, by winding them suitably with conductors. Non-conducting rods could also be used for the electric attraction method after rendering one end conducting and providing a conducting path from this end to the clamp by plating or otherwise. The advantages of fused quartz for such work are patent.

Magneto-striction is a unidirectional effect in nickel. In iron and steel the effect is less, and in some circumstances does not increase with increase in field. There ap-

peared then the possibility that attempts to maintain oscillations by magneto-strictive forces might fail with iron and its varieties, but suc-ceed with nickel. Troubles threatened to arise in consequence of eddy currents and hysteresis. However, it turned out on trial that east steel bars and mild steel bars could be maintained in resonant vibration with very great facility. With nickel the effects are even more striking. Both polarised and unpolarised electrostrictive forces may be employed. In the polarised case a coil carrying a constant current surrounds the middle of the bar, and the oscillating current from a valve set is sent round a coil conveniently wound on the same former. obtain the unpolarised effect, care should be taken that the bar is not magnetised to begin with. If it is magnetised one can very readily obtain the polarised effect; the permanent magnetic state of the bar then performs the function of the direct current. If the induction coil of a 'tuned anode' assemblage with grid coul coupling be itself used to provide the alternating field, then it is convenient to provide a separate winding for the direct current. In this case a galvanometer in the grid coil will indicate the presence of the oscillating bar.

The variations in the deflexions of the grid galvanometer are similar to those in which the set is influenced by a neighbouring resonating circuit, a result in accord with the masterly researches of Butterworth (Proc. Phys. Soc., vol. 27, p. 410). On increasing the capacity very slowly, as resonance is approached, the deflexion falls until a value of the capacity is reached marked by a sudden drop in the current; this fall is immediately followed by a sudden rise to less than the previous value. On reversing the changes in capacity the deflexion decreases and then suddenly rises at a value of the capacity differing slightly from that at which the drop occurred as the capacity was increased. The exact point of resonance lies

between these two values. This method of tuning a valve set to the resonant frequency of a neighbourmg circuit is a modification of Austin's well-known 'double click' method. Both methods are described in Moullin's "Radio Frequency Measurements," pp. 14 and 136. In an experiment on a nickel rod a metre long and 2.54 cm. diameter, the critical points on the condenser scale were separated by an interval of a four thousandth part of the whole capacity. On clamping the bar by means of heavy lead weights these irregularities disappear. Clamping the bar corresponds to breaking the connexions in the neighbouring circuit.

Such experiments need not be confined to bars of one material, nickel or iron could be suitably attached to bars of other materials. Nor need the oscillations be wholly longitudinal, for example, a conventionally shaped tuning fork could be thrown into resonant vibration by subjecting the junction of the prongs to a vibrating magnetic field in the plane of the fork and at right angles to the prongs.

The field producing magneto-striction may be due to a current carried by the magneto-strictive body. Thus when a current traverses a wire of nickel its circumference shrinks and the whole wire will therefore tend to increase in length. Thus Beatson heard a sound produced by an intermittent current flowing in an iron or steel wire (Beatson, Elect. Mag, April 1846). This reference is taken from a remarkably interesting paper by Honda and Shimizu (Phil. Mag., vol. 4, Series Six, p. 645) entitled "Note on the Vibration of Ferromagnetic Wires placed in a Varying Magnetizing Field," and published twenty-five years ago. In their paper the earlier work is reviewed and an account is also given of their own experiments on the subject carried out with such resources as were then available for experimenters. Magneto-strictive oscillations are so readily produced that it may well transpire that materials which when tested by static methods do not exhibit the effect will, when subjected to properly tuned fields, be found to possess it. For example, some variety of invar may be sufficiently magneto-strictive to oscillate in a tuned field; so that in addition to obvious important technical applications such as the provision of sources of oscillations and frequency standards, this method may be of scientific value.

A paper on some parts of this very wide and fascinating subject is in preparation.

#### Standardisation of Telephone Apparatus.

In the article on my paper on telephone apparatus standardisation in NATURE of Nov. 26, the writer states that it is not easy to understand what telephone engineers mean by a transmission unit, and I agree that if reference only is made to the short statement included in my paper this is certainly true. I may, perhaps, therefore be allowed to supplement this statement by the following remarks:

Until recently the telephone engineer expressed losses and gains in transmission efficiency in two ways, namely: (1) in terms of the product of attenuation constant and length,  $\beta l$ ; (2) in terms of a standard

cable having certain definite line constants.

The objection to (1) is that it is strictly applicable only to a homogeneous telephone line of infinite length, and that such lines do not occur in telephone practice, and that, furthermore, the product of attenuation and length is meaningless when applied to a piece of telephone apparatus.

The objection to (2) is that it is arbitrary, and is dependent on the frequency transmitted.

eta l, however, is equivalent to  $\log_s \frac{\imath_1}{\overline{\iota}_2}$  or  $\log_s \frac{v_1}{v_2}$  or  $\log_s \frac{p_1}{p_2}$ , where  $i_1, \imath_2, v_1, v_2$  and  $p_1, p_2$  are input and output currents, voltages, or powers respectively.

In this form the conception of a product of attenuation and length has disappeared, and hence the application to non-homogeneous and short lines and to apparatus generally is logical So far this is the argument for the use of the unit termed the 'néper,'

which is equivalent to  $\frac{1}{2}\log_e\frac{p_1}{p_2}=1$ . The advocates of the unit termed the 'bel,' that is,  $\log_{10} \frac{p_1}{p_2} = 1$ , claim that in this form the relationship between the numerical values of the units and the actual input and output power ratios is much simpler to memorise and more convenient for use by working telephone engineers than when natural logarithmic values of ratios are used, and that as the infinite homogeneous line, on which the unit  $\beta l$  is based, is an abstract conception, there is no advantage in retaining this conception in the form of the natural logarithm of a ratio

In conclusion, it may also be pointed out that transmission values based on the direct ratios of input and output powers could be used to express transmission efficiency, if it were not for the large range of numerical values required, and the fact that a number of individual transmission values would require multiplying together to obtain the overall value, instead of adding as in the case of the logarithms of the ratios

The controversy between the protagonists of the two different systems formed the subject of a number of articles appearing in the Electrician and elsewhere B. S. COHEN. some time ago.

I HAVE read with great interest Mr. Cohen's letter, but regret that I still have only the haziest notions of what the various kinds of transmission units are, about which there is so much controversy. I thought at first they were the 'telephone traffic units,' but as these depend on the calls in a specified period of time (see B.E.S.A. glossary No. 9932) it could not refer to them. Mathematical engineers like Dr. Fleming call  $\beta$  the wave-length constant and  $\alpha$  the attenuation constant. Apparently a distortionless circuit is considered. I assume that a 'homogeneous' circuit is the same as what Heaviside called a distortionless circuit. Until clear, mathematical defini-tions of the 'transmission units' are given, it seems a waste of time to discuss them at international or other meetings.

THE WRITER OF THE ARTICLE.

# John W. Draper's Position in Science.

IN NATURE of Sept. 24 the interesting Calendar of Discovery and Invention states that the first astronomical photographs were made in 1840 by John W. Draper, using daguerreotype plates; also that Draper's last great photographic achievement was a record of the nebula in Orion, made on Sept. 30, 1880, and that attempts at improving on this first effort were cut short by Draper's death. Here, at New York University, where Draper was a member of the faculty during the productive years of his life, we were gratified to see this appreciative note about him. In the interest of accuracy, however, it should be stated that the photographs of the great nebula in Orion were

obtained by Draper's son, Henry, who was in his own right the leader of stellar photography in America The photograph made on Sept 30, 1880, was given 57 minutes of exposure. In March 1881 a better photograph was made by Henry Draper from an exposure of 104 minutes, and on Mar. 14, 1882 (more than two months after the death of John W. Draper), a remarkably successful exposure of 137 mmutes was made, which showed stars of the 147 magnitude of Pogson's scale—stars invisible to the eye. Henry Draper also obtained many excellent photographs of the spectrum of the nebula in Orion Unfortunately, Henry Draper died suddenly on Nov 20 of the same year at the age of forty five.

The reference in the Calendar to the first astronomical photograph undoubtedly means the daguerreotype of the moon made by John W. Draper in 1840 after an exposure of 20 minutes—a representation about an inch in diameter. Daguerre had attempted the feat but without success. John W. Draper experimented in photographing the solar diffraction spectrum on paper before the daguerreotype process was invented, but he did not know how to develop and fix his image, until Daguerre, Talbot, and Herschel worked out their developing and fixing processes. Herschel made the first useful photograph of the solar spectrum in 1840;

Draper did not succeed in this until 1842.

For some time I have been anxious to learn the true evaluation of John W. Draper's place in science. He was a man of such varied interests and was au courant with so many scientific developments that it is difficult to gauge his status. For example, thirteen years before Kirchhoff published his celebrated memoir on the relations between the coefficient of emission and absorption of bodies for light and heat, Draper had arrived at some of these same facts non-mathematically. There is no doubt that Draper contributed importantly to the advancement of knowledge of radiant energy. Just how much credit is due to him for his varied researches is the question

# A Theory of the Upper Atmosphere and Meteors.

There seems to be a factor omitted by Mr. Maris in the second paragraph of his letter in NATURE (Dec. 10, p. 839) which may modify somewhat the figures he gives. If the constituents of the atmosphere were uniformly mixed at all altitudes and then left free from convection currents, there would be a partial separation into lighter and heavier particles undoubtedly, but the level reached by the diffusing

gases would be conditioned by three factors.

These will be realised readily if we remember that the earth is, in fact, a huge centrifuge and (neglecting convection currents, together with the steady flow into space of some of the lightest particles) the equilibrium position of any constituent depends on (1) gravity, (2) centrifugal force (if I may be pardoned for using such an old-fashioned expression), and (3) osmotic pressure. (2) is small compared to (1), and our centrifuge is therefore one in which the heavier particles converge inwards, but this movement is arrested by (3) just as in an ordinary centrifuge. Unfortunately, so far as I am aware, the osmotic pressure of a mixture of gases has not been determined; I would, however, suggest that if the 'optical centrifuge' described by me (NATURE, Dec. 10, p. 840) were charged with a mixture of argon and hydrogen, some light might be thrown on the subject.

#### Further Hominid Remains of Lower Quaternary Age from the Chou Kou Tien Deposit.

Ar a meeting of the Geological Society of China. held on Dec 2, 1927, announcement was made of the discovery of a lower molar hominid tooth in the cave deposit at Chou Kou Tien, near Peking. The new specimen was obtained close to the site from which the first hominid teeth from this locality were recovered and in the same stratum of the deposit (NATURE, Nov. 20, 1926, p. 733) This deposit, which at first was thought to be Upper Phocene, is now known to be basal Lower Quaternary in age (very early Pleistocene) The find was made on Oct. 16 by Dr Birger Bohlin, paleontologist attached to the Geological Survey of China. Mr. C. Li, geologist from the Survey, and Dr. Bohlin have been in charge of the extensive excavations on this important site, which have been carried on during the past season by the Geological Survey in co-operation with the Department of Anatomy of the Peking Union Medical College

The tooth is a relatively unworn and perfectly preserved lower permanent molar, having incompletely formed root tips, and evidently from an individual in the stage of development represented by that of an eight year old modern European child. The general morphology of this specimen leaves no room for doubt as to its hominid status, and it evidently was derived from the same jaw as that from which came the lower premolar tooth discovered last year by Dr. O. Zdansky. A full description of the latter specimen and of the associated worn upper molar has been published this year by Dr. Zdansky (Bull. Geol. Soc. China, vol. 5, No. 3).

Evidence of a convincing nature points to a close mutual relationship between the two individuals, adult and immature, represented by the teeth recovered from the Chou Kou Tien deposit. The newly discovered specimen displays in the details of its morphology a number of interesting and unique characters, sufficient, it is believed, to justify the proposal of a new hominid genus Sinanthropus, to be represented by this material. A complete and fully illustrated report on this new specimen is now in press, and will be published early in December in Series D, Palæontologia Sinica, vol. 7, Fasc. 1.

### The Publications of the Royal Society.

It would be a pity if—as, of course, cannot be intended—the remarks in the leading article of Dec. 17 were taken, among an uninstructed public, to imply some disparagement of the scientific quality of the output of the Cavendish Laboratory in proportion to its extent. In the present avalanche of theories of atomic processes and radiation, what appears to be necessary more than ever is precise and informed experiment in this complex and elusive domain. Where are we likely to secure these ideals if not in a company where all the practical experience of all the ages of radio-activity is concentrated? At any rate, it may be permitted to record the judgment of one outside student of current physical literature, that it is not there that the fault, if any, is to be located.

Joseph Larmor.

Cambridge, Dec. 19.

#### The Antirachitic Vitamin D.

WHILE the chemical nature of the six known vitamins remains obscure, recent advances in knowledge have brought us very much nearer to understanding that of one of them, namely, the antirachitic vitamin D. This has been brought about through the work of Rosenheim, Webster, Drummond, Heilbron, Hess, and Windaus, some of whom have now shown conclusively that vitamin D may be produced in a highly concentrated form from a pure crystalline substance, ergosterol, merely by acting upon it with sunlight or the radiation from a mercury-vapour lamp. This discovery is of great practical as well as scientific importance

Following the observations that the cure of infantile rickets was brought about by exposure of the body to ultra-violet light and by administration of cod-liver oil, it was found that a number of foodstuffs containing cholesterol, after exposure to ultra-violet light, were rendered effective as curative agents for rickets artificially induced in rats by previously feeding them on a diet devoid of vitamin D. From this the workers referred to were led to study cholesterol, ergosterol, fungisterol, and  $\alpha$ -,  $\beta$ and y-sitosterols. At first it appeared that each of them developed activity under the influence of ultra-violet irradiation; but later it was shown that these compounds can only be purified with some difficulty, and it was proved that cholesterol and  $\beta$ - and  $\gamma$ -sitosterol when completely purified can no longer be activated by irradiation, and there is reason for supposing that the same will be found to be true of a-sitosterol and fungisterol. On the other hand, all the evidence goes to show that ergosterol is the sole antirachitic precursor

If this be so, then ergosterol must be present in practically all fats of animal or vegetable origin, for all of these are capable of activation by irradiation, but it is found chiefly in fungi—in ergot of

rve and in yeast

When ergosterol is exposed to ultra-violet irradiation, it loses its crystalline character and becomes resinous. Oxygen does not appear necessary for this change, which can in fact best be effected in vacuo or in an atmosphere of nitrogen. The resinous substance thus formed is very highly active in curing rickets. The activity is, however, destroyed if the irradiation be long continued Irradiated ergosterol has been found to possess remarkably powerful physiological activity; indeed, Miss K. H. Coward has shown that its calcifying effect can be demonstrated with so little as 1/100,000 mgm administered to a rat in daily doses

Of the vitamins, vitamin D is the one which pre-eminently needs to be artificially added to the diet, especially in sunless climates. The reason for this will be clear when it is considered that it is chiefly formed in animals rather than in plants, and results from exposure of the animal to sunlight or to a source of ultra-violet rays. It is well known that the sebaceous glands contain sterols and sterol esters, and there is good evidence for believing that it is from this source that the animal derives its

antirachitic vitamin It has been shown, moreover, that the liver acts as a storehouse for this vitamin when produced, and that a reserve is set up in the animal during the summer months, by which it is enabled to maintain good health during the winter It has been shown, too, that, as a consequence of the impoverishment of the store, the milk of a cow contains progressively less vitamin D as the winter months proceed. Milk and butter provide the most important dietetic sources of this vitamin; and for this reason, and because of the weakness of the sun's rays in winter, human kind suffer then impoverishment in respect of vitamin D, which is neither produced by the action of the sun's rays on their skins nor supplied in their diet in adequate amount

Vitamin D appears to be necessary to the animal body for the proper control of the calcium balance, and a lack of it results in a depression of the phosphorus or calcium, or of both, in the blood. Moreover, the more cereal there is in the diet, especially oatmeal, the greater is the amount of vitamin D required. Its practical importance is by no means limited to the prevention or cure of rickets, but applies also to other conditions causing greater or less ill-health and suffering It has, for example, already been shown by the admirable work of Prof. and Mrs. E. Mellanby that dental caries may be traced to a deficiency of vitamin D. From their work it would appear that, in a growing child, bone formation makes a first call on the calcium metabolism and may rob the teeth unless sufficient or an excess of vitamin D is provided. Indeed, dentists throughout England can point to innumerable examples of dental caries traceable to the substitution of margarine for butter during the War. In childbirth the drain on the mother is well known to result in dental caries, and there is strong reason for supposing that this could be prevented by the administration of more vitamin D.

The growth of population is such that the world production of butter is becoming insufficient to provide for all an adequate ration of vitamin D. Cod-liver oil provides another source of vitamin D, but irradiated ergosterol has the great advantage of being practically without taste. Moreover, it is less expensive, and being of standard purity the amount administered can be quantitatively adjusted with great accuracy.

The practical outcome is that the manufacture of ergosterol from yeast has been set up in Great Britain, and it is being irradiated commercially under proper scientific control with animal tests. Consequently vitamin D can be provided sufficient to meet the world's requirements. English manufacturers are issuing it in pellets or capsules and in oily solution, also in combination with vitamin A and malt extract, so that it is easy for all to make good the deficiency due to climatic influences during the winter months. Thus no time has been lost in applying this discovery of science to essentially practical ends.

# Atoms and their Packing Fractions.1

By Dr. F W. Aston, F.R.S.

THE original mass-spectrograph was set up in the Cavendish Laboratory in 1919 resolving power was sufficient to separate mass lines differing by about 1 in 130, and its accuracy of measurement was about 1 in 1000 These capabilities sufficed to determine with fair certainty the isotopic constitution of more than fifty elements, and to demonstrate that. with the exception of hydrogen, the masses of all atoms could be expressed as integers on the scale O = 16 to one or two parts in one thousand. For advance in two directions of fundamental importance, namely, the resolution of the mass lines of the heavier elements and the measurement of the divergences from the whole number rule, a considerably more powerful instrument was required and has now been constructed. The increase in resolution is obtained by doubling the angles of electric and magnetic deflexion, and sharpening the lines by the use of finer slits placed farther apart. The new instrument has five times the resolving power of the old one, far more than sufficient to separate the mass lines of the heaviest element known. Its accuracy is 1 in 10,000, which is just enough to give rough first order values of the divergences from whole numbers.

Such a high order of accuracy can be attained only when lines are so near together on the mass spectrum that not only can their distance apart be determined with the highest accuracy but also the calculation of their mass difference will not be seriously affected by error in the dispersion constant. These conditions may be made use of in several different ways, as follows:

Method I.—Direct measurement on a single spectrum. This method is virtually free from all uncertainty, but can only be applied to bodies giving lines clearly resolved, but differing by less than I per cent. in mass. These cases are unfortunately very rare. The best example is the doublet given by oxygen-methane shown in spectra I. and IV. (Fig. 1). Here the lines only differ by 0.2 per cent. in mass, and can be obtained of equal intensity by manipulation of the quantities of oxygen and methane present in the discharge tube.

Method II, which may be called the method of series shift, can be employed whenever the masses to be compared form terms in a series the unit of difference of which is not too great. Two potentials are chosen which will bring consecutive terms into the desired contiguity, and these are applied to the electric plates alternately during the exposure while the magnetic field is kept constant. In this way irregularities in the series can be measured. A good example of this is shown in spectrum II. where the series 79, 80, 81, 82 given by bromine and its hydrides is tested in this way and the interval between Br79 and Br80 determined in terms of the hydrogen atom.

<sup>1</sup> From the Bakerian Lecture—A New Mass-Spectrograph and the Whole Number Rule, *Proc. Roy. Soc.* A, vol. 115, p. 487, 1927, to which the reader is referred for all details of apparatus and technique

Method III is the most generally applicable. It is the original bracketing method modified by the use of a small interval instead of a bracket the lines are brought into the required contiguity by a change in the electric field, and this change is measured by means of two other mass lines of known ratio.

In the calculation of atomic masses from the ratios measured, the atom O<sup>16</sup> is taken as the standard of mass The results so far support the conclusion that oxygen is a simple element and that therefore this scale is the same as that used in chemical atomic weights

Ever since the discovery of the whole number rule, it has been assumed that in the structure of atoms only two entities are ultimately concerned, the proton and the electron If the additive law of mass was as true when an atomic nucleus is built of protons plus electrons as when a neutral atom is built of nucleus plus electrons, or a molecule of atoms plus atoms, the divergences from the whole number rule would be too small to be significant. and, since a neutral hydrogen atom is one proton plus one electron, the masses of all atoms would be whole numbers on the scale H = 1. The measurements made with the first mass-spectrograph were sufficiently accurate to show that this was not true. The theoretical reason adduced for this failure of the additive law is that, inside the nucleus, the protons and electrons are packed so closely together that their electromagnetic fields interfere and a certain fraction of the combined mass is destroyed. whereas outside the nucleus the distances between the charges are too great for this to happen. The mass destroyed corresponds to energy released, analogous to the heat of formation of a chemical compound, the greater this is the more tightly are the component charges bound together and the more stable is the nucleus formed. It is for this reason that measurements of this loss of mass are of such fundamental importance, for by them we may learn something of the actual structure of the -nucleus, the atomic number and the mass number being only concerned with the numbers of protons and electrons employed in its formation.

The most convenient and informative expression for the divergences of an atom from the whole number rule is the actual divergence divided by its mass number. This is the mean gain or loss of mass per proton when the nuclear packing is changed from that of oxygen to that of the atom in question. It will be called the 'packing fraction' of the atom and expressed in parts per 10,000. Put in another way, if we suppose the whole numbers and the masses of the atoms to be plotted on a uniform logarithmic scale such that every decimetre equals a change of 1 per cent., then the packing fractions are the distances, expressed in millimetres, between the masses and the whole numbers.

In Table I. is given a list of elements on the isotopic constitution of which further light has been

No. 3035, Vol. 1201

of non-radioactive isotopes discovered up to the present

Table II. gives a list of the precision measurements including those calculated for lithium from Costa's results. The margin of error given may be

TABLE II.

Atom	Packing fraction × 101	Mass 0 = 16	Atom	Packing fraction × 101	Mass O =16
Xer Mer	77 8 ± 1 5 5 4 ± 1 20 0 ± 3 17 0 ± 3 13 5 ± 1 5 10 0 ± 1 · 5 30 ± 1 5 · 7 ± 2 0 0 0 · 0 + 1 0 · 2 ± 1 (2 2	pes) . pes)	Cl <sup>35</sup> A <sup>36</sup> Cl <sup>37</sup> A <sup>40</sup> As Kr <sup>78</sup> Br <sup>79</sup> Kr <sup>80</sup> Kr <sup>81</sup> Kr <sup>84</sup> Kr <sup>84</sup> Kr <sup>84</sup> Hg <sup>200</sup> Ph <sup>206</sup>	$\begin{array}{c} -48 \pm 15 \\ -66 \pm 15 \\ -66 \pm 15 \\ -50 \pm 15 \\ -72 \pm 1 \\ -88 \pm 15 \\ -94 \pm 2 \\ -90 \pm 15 \\ -91 \pm 2 \\ -86 \pm 15 \\ -88 \pm 1$	34 983 35:976 36:980 39:971 74:934 77:926 78:929 79:926 80:926 81:927 82:927 83:928 85:929 126:932 119:912 133:929 200:016 206:016

regarded as an outside limit, hence it is large in all cases where comparisons are made indirectly. The masses of the atoms are simply calculations from the packing fractions, so no particular significance is to be attached to the final digit. The agreement with chemical and other results is generally good in cases when such agreement is to be expected, but the best test of the accuracy of the measurements is their consistence among themselves. So far this is highly satisfactory, and makes it reasonably probable that most of the packing fractions are within one unit of their true value.

As has already been explained, in addition to the first two fundamental constants of an atom, atomic number and mass number, which settle the numbers of protons and electrons contained in its nucleus, we now have a third, the packing fraction, which gives entirely new information on the nucleus, for it is a measure of the forces binding those protons and electrons together The discriminating value of this information is clear at once, for example, had the packing fraction of the helium atom not

been greater than that of the oxygen atom it would have ruled out the possibility that the nucleus of the latter was simply built of four unchanged helium nuclei or alpha particles, for there would have been no loss of energy, that is, mass detect, in the latter to represent the binding forces holding the four particles together. High packing fractions indicate loseness of packing, and therefore low stability low packing fractions the reverse. We are at once led to inquire into what happens to the packing fraction as we ascend from atom to atom in the scale of mass.

The result of plotting packing fractions against mass numbers for all atoms so far investigated is indicated in Fig. 2. Fig. 3 gives the same plot for the light elements on a larger scale. These indicate that the packing fraction as a function of mass number shows simple regularities of a remarkable kind. If we ignore for the present the large gaps

which it is hoped to bridge as the work proceeds, it appears that all atoms, except those of light elements of even atomic number, approximate to a single curve. Starting at hydrogen with a large positive packing fraction, the curve drops rapidly, crosses the zero line in the region of mass number 20 and sinks to a mmimum value Very recent experiments with nickel give a provisional value - 10 for the packing fraction of its lighter isotope Ni<sup>58</sup> This is the lowest obtained, and suggests that the minimum is in the iron nickel region, which may have a significance in connexion with the presumed geological abundance of these elements. The curve then rises again and recrosses the

zero line in the region 200 There is no marked periodicity

As was to be expected, the most interesting region is that of the lightest atoms, shown in Fig. 3. In isotopic constitution and relative abundance there is a fundamental class difference between elements of odd and elements of even atomic number <sup>3</sup> This is reflected in the behaviour of their nuclei under the disintegrating impact of alpha particles, for Rutherford and Chadwick have shown that odd numbered elements have less stable nuclei and emit protons at a much higher average speed than those of even number. This difference is now shown to extend to their nuclear masses. Whereas the atoms of odd atomic number, irrespective of whether their mass number is odd or even, approximate to a smooth curve rising steeply to hydrogen, those of even atomic number lie well below and may be said to form a branch rising less steeply to helium. For comparison, the rectangular hyperbola x (y+125) = 250 has been drawn in Fig 3 Such a curve is the locus of the packing

fractions atoms of mass = mass number + 1/40 unit, if  $O = 16 (1 + 12.5 \times 10^{-4})^{-1}$ 

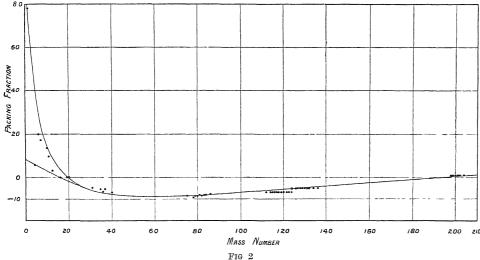

In the cases of atoms of odd atomic number the measurements show a definite approximation to this curve. This means that the masses of the nuclei of these particular atoms can be regarded as

who claim that protons can be detached from these nuclei by the impact of alpha rays. Neither do the observations of Rutherford and Chadwick that the chance of disruption of protons from lithium atoms, if possible at all, is small compared with those of boron, nitrogen, etc., show any serious discordance

with Costa's results for lithium, here plotted, for the position of these suggests that their nuclear structure, though loose, is not so loose as that of the others. It is unfortunate in this connexion that data for beryllium are not available.

The fact that the packing fractions of the heavier atoms show a smooth distribution and do not decrease continually with increase of mass number

of mass number is interesting. It is not what one would expect were the nucleus a structure similar to the outside of the atom, and possessing a periodic function. It is much more in keeping with the view put forward by Sir Ernest Rutherford 4—that the nucleus consists of an inner part of uniform, tightly bound

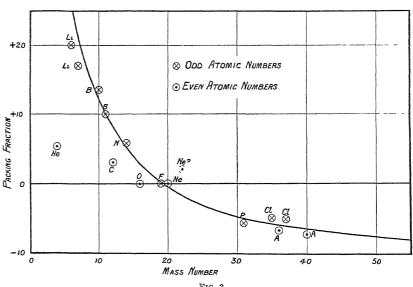

being made up of two distinct parts, one which changes by unity for each unit advance in mass number, and another, a small excess, which remains constant. To illustrate this point we may imagine the nuclei of these atoms to consist of a central core of maximum tightness of packing, correspond-

ing to a packing fraction on the oxygen scale of -125, which is surrounded by, let us say, three protons or neutrons attached with a tightness represented by a packing fraction 83 3. That is to say, these three bodies will together account for the excess 1/40 unit. The free proton has a packing fraction on the new scale of 778 + 12.5 = 90 3 which leaves a balance of 7 for binding purposes in each case.

No stress is to be laid on these figures which are purely illustrative, nor is it intended to discuss the possibilities in any detail at present, but the facts do certainly suggest that the nuclei of light atoms have a loose, and therefore heavy, external structure of lightly bound protons or neutrons common to them but not possessed by

the much more stable and tightly bound atoms of helium, carbon, and oxygen. Whether this is so or not, the position of carbon and oxygen on the diagram indicates a tightness of packing entirely in favour of the views of Rutherford and Chadwick as against those of Kirsch and Pettersson,

'crystalline' structure, outside which is a looser system of neutrons, protons, and electrons which is more complex the heavier the element. The crystalline packing supplies a minimum possible packing fraction, while the increasingly complex outer structure may be taken to explain the rise of the packing fraction in very heavy elements.

<sup>4</sup> Guthrie Lecture of the Physical Society of London, 1927

Baron de Montyon, F.R.S. (1733-1820), and the Paris Academy of Sciences.

ANTOINE JEAN ROBERT BAPTISTE AUGET, Baron de Montyon, economist and philanthropist, was born at Paris on Dec 23, 1733, and he died there on Dec 29, 1820, at the is held in honoured remembrance for his public work and enlightened beneficence. Whilst domiciled in England-for reasons which are given below—de Montyon was, on Nov. 5, 1812, elected into the Royal Society of London Soon after, he signed the charter book and was formally admitted

Trained in France for the law, Montyon held various important provincial and State appointments, exhibiting marked independence of thought and freedom from bias, associated with an integrity certainly none too prominent amongst some of his

contemporaries.

Prior to the period of revolutionary turmoil, M. de Montyon ĥad made anonymous and handsome donations to the Paris Academy of Sciences, the French Academy, and the Academy of Medicine. These became null and void in the political upheaval. They were, however, restored before his death.

De Montyon, rich by inheritance, and disinclined to parley with any new regime, emigrated in 1792, settling for a time at Geneva, afterwards transferring to London. He did not return to Paris until 1815, being then eighty-two years old. Count Rumford had died in the previous year; Davy was then thirty-seven years old The English journals of the period of de Montyon's residence in London are provokingly silent, although two works by him had been published there. Space will not permit of quoting their lengthy titles.

Appended is a copy of de Montyon's certificate

of qualifications for the Royal Society:-

"Anthony J. B. R. Auget de Montyon, Baron de Montyon, Counsellor of State in the late Royal Government of France, and now residing at No. 38 Brewer Street, Golden Square; a gentleman of eminent acquirements in political economy and various branches of Natural Knowledge, being desirous of becoming a fellow of the Royal Society, We the underwritten do on our personal acquaintance with him, recommend him as worthy of the honor he solicits, and likely to become a valuable Member. C. Blagden, John Symmons, J. Planta, Samuel Foart Simmons, Wm. Tooke, J. Guillemard, John Sinclair, Gilbert Blane, Geo. Thos. Staunton, Geo. Pearson.'

It is not a little curious that de Montyon seems never—either before or after his election—to have dined at the Royal Society Club, especially when one calls to mind that Sir Joseph Banks was president of the Society at the time, and frequently introduced foreigners of distinction. M. Coquebert de Montbret, a compatriot, was among these, and he dined, so Sir Archibald Geikie has told us, on four occasions after 1809. Here it may be interpolated that de Montbret was, with Laplace and Fourier, on a commission for the institution of the Montyon prize in statistics (1817). Doubtless sufficient reason is found in the quietness of Montyon's life, necessitated by the circumstances

of exile. Moreover, he had never sought the fashionable world, preferring the society of men of It is recorded that he was a good conversationalist, and prolific in attractive reminiscences. Whilst in England he disbursed large sums of money in support of companions in exile, and also amongst the French prisoners of war. His portrait shows an aspect of restful dignity, singu-

larly resembling that of Newton.

At Montyon's obseques strict simplicity was His own wishes in this respect were "Je veux être enterré avec la plus observed grande simplicité, ce qui doit être exécuté d'autant plus exactement que ce qui sera économisé sur cet article tourne à l'avantage de mes legs." Notwithstanding, hundreds of folk of the humbler classes attended in token of regard. The French Academy nominated one of its members to deliver a eulogy. In the twilight of his age Montyon had recalled words that he used to the King in 1796: "Ma vie n'a pas eu un grand éclat. mes actions qui ont eu une publicité indispensable prouvent que je n'ai point l'âme servile."

The prizes which are in the gift of the Academy of Sciences are enumerated below; and some notes added indicate slight variations which have followed

their institution.

(1) PRIX MONTYON DE STATISTIQUE —At a meeting of the Academy in September 1817, Laplace informed his colleagues of an anonymous offer of a capital sum of 7000 francs for the establishment of an annual prize for statistical researches. Acceptance followed, and Laplace, Montbret, and Fourier were among the members of a commission charged to prepare a scheme of management. The first allocation was made in 1819 In the year 1910, on the motion of M. Gaston Darboux, a sum of 1000 francs was decided on as the primary gift, with two commendatory awards of 500 francs. Further, an original limitation that the research should refer only to France and her colonies, is no longer enforced.

(2) Prix Montyon de Physiologie expéri-MENTALE -In June 1818 the Academy received another offer, in similar circumstances, for the foundation of a yearly prize in experimental physiology. Berthollet, Hallé, and others drew up a scheme. Later, the donor supplemented the gift. As a rule there are two awards of 750 francs each. We notice here and there in the list of awards the names of Englishmen, for example: Dr. A. D. Waller (1887) and Dr. A. B. Griffiths (1893).

(3) PRIX MONTYON DE MÉCANIQUE —In August 1819, Laplace presented a note designating this annual prize, and from the same source. The attribution is now 750 francs. In exact terms the gift is for . . . "instruments utiles aux progrès de l'agriculture, des arts mécaniques et des sciences

pratiques et spéculatives."

(4) PRIX MONTYON DE MÉDECINE ET CHIRURGIE ET PRIX MONTYON DES ARTS INSALUBRES.—This conjoint prize was dedicated by the terms of Baron Montyon's will, under date Nov. 12, 1819. There were other and large benefactions, which, however, are outside the scope of this notice—The first prize was given in 1825—A commission had formulated regulations, and amongst the members were Cuvier, Fourier, and Berthollet. The terms of the award are of wide application, whilst the prizes are open

to persons of all nationalities — In the first section are three yearly gifts of 2500 francs, and three mentions honorables of 1500 francs — In the second section (in effect, chemistry) there is a prize of 2500 francs, with a second of 1500 francs for meritorious entry. — T. E. James.

#### News and Views.

FOR several years Dr. Wilhelm Freudenberg has collected fossils from the sand-pits in the Pleistocene river deposits near Heidelberg, from which the lower law of Homo heidelbergensis was obtained. We now learn, from a communication which he has made to Sir Arthur Smith Woodward, that among the mammalian remains which he has discovered there are no less than eighteen fragments of fossil man and apes. The tibia ascribed to Heidelberg man is short and very stout, with an inward twist, and in many ways like that of a big gorilla. A fragment of a femur is also very gorilla-like. The second metatarsal is curved as in a chimpanzee, and the first metacarpal is twice as large as that of a modern man. These remains are associated with Elephas antiquus. Other fragments found not with this elephant, but with E. trogontherm, belong to a Primate about as large as an orang. There is a sagittal crest on the parietal bone, and a piece of lower jaw resembles that of Sivapithecus rather than Dryopithecus pelvis shows several features of that of a chimpanzee, and the femur and tibia are slender. Other fragments of the same age belong to two smaller Primates related to the gibbons. They seem to have had comparatively small canine teeth. In association with them, one long and remarkably human femur, an apparently human pubis, and a human navicular bone, are considered by Dr. Freudenberg to belong to a forerunner of Neanderthal man. In the upper beds, with Rhinoceros etruscus, were also found implements of quartzite, charcoal, and burnt fragments of bone.

PALÆONTOLOGISTS and anthropologists will await with great interest Dr. Freudenberg's detailed description of his finds. Remains of monkeys of Pleistocene age are known from Norfolk, the Thames valley, France, and Germany, but no trace of the man-like apes has hitherto been discovered in Europe of later date than the Lower Pliocene. If Dr. Freudenberg's results are confirmed, the search for the earliest ancestors of man in Europe is not so hopeless as it is commonly supposed to be.

The retirement is announced in the *Lancet* of Dr. A. B. Macallum, professor of biochemistry in McGill University, Montreal, and formerly administrative chairman of the Honorary Advisory Council for Scientific and Industrial Research, Canada Prof. Macallum, who was successively lecturer and professor in physiology and later professor of biochemistry in the University of Toronto, introduced a full experimental course in physiology at Toronto so long ago as 1886; at that time, no similar course for students was anywhere in existence. His research work at first

was devoted particularly to the origin of hamoglobin from the chromatin of hæmatoblasts This led to a demonstration that chromatin is an iron-holding compound and that hæmoglobin is, as it were, a degeneration product of chromatin. Later, Prof. Macallum investigated the absorption of iron compounds in the intestines, the composition of the blood plasma of invertebrates and vertebrates, and the microchemical detection of potassium, chlorine, phosphorus, calcium, iron, and copper. His latest work has dealt with the effects of surface tension on the distribution of salts in living matter. Macallum was elected a fellow of the Royal Society m 1906, in 1920 he left Toronto to take the chair of biochemistry at McGill University. He will be succeeded by Prof. J. B. Collip, whose name will be remembered in connexion with the discovery of ınsulın.

The honorary secretary of the Institution of Professional Civil Servants writes to inform us that the leading article on "The Technical Expert in the Civil Service," published in our issue of Dec. 10, has been welcomed by the professional group of civil servants. He directs attention also to the fact that, since its foundation in January 1919, the Institution has worked energetically for "a thorough reform in matters affecting the status of the technical expert," and has met with some success over a limited area in bringing conditions of employment of similar professional staffs in different departments to a uniform basis Further, by recourse to the arbitration machinery set up for the Civil Service in 1925, it has succeeded over a rather wide area, but in many cases, in obtaining piecemeal improvements in salary scales. He also points out that the reform of the non-technical branches of the Civil Service was only carried through after a series of Royal Commissions, and states that, although the Council of the Institution has loyally worked the system of Whitley Councils recently created, it is convinced that the reforms which are urgently required in the technical branches will not be achieved without an authoritative public inquiry. We entirely concur in this view, and, indeed, in the leading article on "The Expert in the Civil Service" published in Nature of Aug. 27 last, urged that a Royal Commission should be appointed to examine into and report on the present position of professional workers in the State service. We are of opinion that the need for modifications of the present Civil Service system is of pressing importance, and that in the interest of both efficiency and economy no time should be lost in providing for a comprehensive inquiry of the nature indicated.

SPEAKING at Sexev's School, Bruton, Somerset, on Speech Day, Prot John Read, professor of chemistry at the University of St. Andrews, directed the attention of the boys of his old school to some of the qualities which scientific training educed. honesty, perseverance, precision, the co-ordination of hand, eye, and brain, the development of logical methods, and the recognition of the importance of small things. Whilst confessing his enthusiasm for literary pursuits, he urged them not to be misled by references to the 'dry bones' of science, or to imagine that the man of science is less human or humane than his brethren, there is need to emphasise this in an age when no man can claim to be truly educated unless he possesses a knowledge of the general principles of physical science and comprehends how a plant grows and how an animal lives. Discussing the everexpanding part which science is playing in the industrial and economic development of the British Empire, Prof. Read referred to the activities of Imperial Chemical Industries, Ltd, and particularly to its progress in rendering Great Britain less dependent on imported liquid fuels and fixed nitrogen, and to its assistance in the development of agricul-Prof. Read also addressed the school literary and debating society on the contribution of organic chemistry to the progress of civilisation, the title of his lecture being "An Organic Chemist looks at the World"; he referred on this occasion to the nonpermanence of coal and oil as sources of energy and to their possible replacement by alcohol, which can be produced in unlimited quantity so long as the sun shines and plants grow. Mention was also made of the low-temperature distillation of coal, and of the value of brown coal as a source of energy

Ar a meeting held at the Imperial College of Science in February last, it was agreed to form a society for the purpose of studying bibliographical methods and securing unity of bibliographical procedure and classification. The first meeting of the Society was held at the Science Library, South Kensuigton, on Dec. 13, thirteen members being present. The objects of the Society were defined as follows: "To promote the study of bibliographical methods and of the classification of information, to secure international unity of bibliographical procedure and classification, and to foster the formation of comprehensive and specialist bibliographies of recorded information." The name adopted for the Society was "The British Society for International Bibliography." As the Society has been adopted as the British Section of the Institut International de Bibliographie, it is proposed to use the sub-title "British Section of the I.I.B." if necessary. Prof. Alan Pollard, of the Imperial College, was appointed president, with Dr. S. C. Bradford, of the Science Library, as vice-president, and Dr. Walter Clark, also of the Science Library, as honorary secretary. The other members of the council are Miss Snelus, Messrs. P. K. Turner, A. Esdaile, and T. Smith. At the VI<sup>o</sup> Conférence Bibliographique Internationale, held in Brussels in July last, it was agreed to confer the presidency of the Institut International de Biblio-

graphic upon Great Britain for the year 1927–28, and the British Society for International Bibliography was invited to nominate the president. It has proposed the name of Prof Pollard. The Society is prepared to receive all criticisms and suggestions for the development of the Classification Décimale of the Institut International de Bibliographie, and to transmit recommendations to the Institute. All particulars concerning the Society, the Institut International de Bibliographie, and the Classification Décimale may be obtained from Dr Clark, hon, secretary of the Society

A MACHINE which is capable of turning out one million pint bottles a week, and requires only one man to superintend its operation, is surely a remarkable achievement. Such is the machine recently constructed by the Metropolitan-Vickers Electrical Co., Ltd., at its works in Manchester (Fig. 1). The glass is melted in pots or in a tank furnace and the machine is run on rails to the mouth of the furnace A small 15-h p. electric motor is started and bottles are automatically turned out in dual moulds at the above rate. The machine consists of fifteen identical

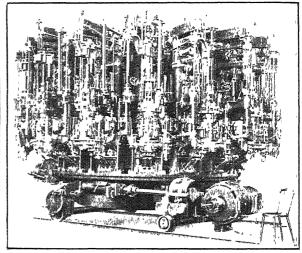

Fig 1

units which rotate around a central pillar. In the event of a breakdown of any one unit, it can be replaced in less than thirty minutes. As each unit passes the mouth of the furnace, huge arms are lowered into the molten glass, a quantity of which is picked up in a mould by means of suction. A small quantity of compressed air is then admitted to form a cavity in the neck of the bottle. Further rotation of the machine, which has a speed of six revolutions per minute, enables the glass blank thus formed to be transferred to a second mould, the interior of which is of the shape of the finished bottle. A further supply of compressed air blows the bottle to the shape of the mould. The machine moves on to the next stage, when the moulds are lowered and the bottles are automatically discharged on to a conveyor. In addition to the manufacture of bottles, this machine is equally useful for the manufacture of electric lamps

or other articles of a similar nature and is entirely a British production. It is a great improvement over previous machines, most of which are of foreign manufacture. For a complete illustrated description of the machine, reference should be made to the *Engineer* of July 1 and 8, 1927.

Mr. L. J Kettle, the electrical engineer to the Dublin Corporation, gave an interesting address to the Irish local centre of the Institution of Electrical Engineers on Oct. 13. He pointed out that the Electricity (Supply) Act, 1927, of the Irish Free State gives practically unlimited power to the Irish Electricity Supply Board. One of its duties is to investigate the natural power resources of the Free State. Towards the end of the War, some work in this direction was done by the British Government. Mr Kettle regards peat as the greatest potential power asset. Six million tons of air-dried peat are at present dug out and used per annum in Ireland. The fuel equivalent of this peat is equal to that of the whole of the coal imported per annum into the Free State. With a little State assistance and encouragement the output could be materially increased. Even if the increase were only ten per cent., it would be equivalent to all the power to be obtained initially from the River Shannon. Mr. Kettle is strongly of opinion that a comprehensive water-power survey of Ireland should be made as soon as possible. It is quite conceivable that the by-products of a peat power station would more than cover all the costs of production, and thus the electric power generated would cost nothing He urged that the Electricity Board should completely equip the model farm near Dublin with all manner of electric labour-saving devices. It would be a valuable demonstration and training centre for the propagandists who are anxious to see the whole country electrified. He pointed out that the actual production costs are now of secondary importance, owing to the large number of middlemen interposed between the manufacturer and the consumer. His cure for this state of affairs is to return to the old village industry system. He considers that a return to this system may be teasible in Treland.

Mr. C. C. Paterson, Director of the Research Laboratories of the General Electric Co., Ltd., gave an interesting address to the London Section of the Institute of Metals on Nov. 10. He pointed out that the cost of conducting materials is one of the heaviest items of expenditure in the electrical industry. For long-distance power transmission it is nearly half the total cost. In addition, it is now becoming common practice to use tubular conductors in order to prevent the formation of the corona. This adds to the expense. It is not beyond the bounds of possibility that metallurgical research will yield a high conductivity alloy which will replace copper. The possibilities of the lighter metals like bervllium and aluminium when alloyed have not vet been fully investigated. So far as the magnetic qualities of metals are concerned, it looks as if the manufacturing departments lag behind laboratory research, at least

so far as heat treatment and new methods are concerned. Practical men now recognise the great importance of the presence of gases in metals like nickel and tungsten which are used in the manufacture of electric lamps. Commercially pure metals from the factory are quite unsuitable for lamp manufacture. A two-hour treatment in 'a vacuum' is necessary until the pressure falls to 0004 mm. of mercury. It would be a great boon to the electrical industry if the metallurgist could produce an alloy in the form of wire which would keep its homogeneous nature, and retain its qualities however long it was subjected to the action of heat In other words, it must remain stable and not develop local hot spots when heated by an electric current It is of great importance to devise tests on the effects of heating on various alloys so as to enable the purchaser to get the most economical material. At the Research Laboratories of the General Electric Co., Ltd., at Wembley, experiments are being carried out on various test methods.

It is announced that Sir Ernest Rutherford has been elected a foreign associate of the Paris Academy of Sciences. The foreign associates of the Academy are limited in number to twelve, and include Sir Ray Lankester, elected in 1910, and Sir J. J. Thomson, elected in 1919.

THE Catherine Wolfe Bruce gold medal of the Astronomical Society of the Pacific, given annually for "distinguished services to astronomy" upon the nominations made by six of the world's great observatories, has been awarded for 1928 to Dr. W. S. Adams, Director of the Mount Wilson Observatory. The formal presentation will be made in the early part of next year. Provious recipients have included Prof. E. W. Brown, M. Henri A. Deslandres, Sir Frank W. Dyson, M. E. B. Baillaud, Prof. A. S. Eddington, and Prof. H. H. Turner.

At a special general meeting of the Institute of Physics, held on Dec. 16, and on the recommendation of the Board, the Royal Meteorological Society was admitted a participating society of the Institute. The Royal Meteorological Society is the sixth society to co-operate in the scheme of participation, and an important step is thus taken towards the realisation of one of the principal objects of the Institute, as expressed at its foundation, namely, to co-ordinate the work of all existing societies concerned with the science of physics and its applications.

COL CHARLES LINDBERGH has been awarded the Langley Medal for Aerodromics of the Smithsonian Institution of Washington, "in recognition of his daring non-stop flight from New York to Paris on May 20 and 21, 1927." Established in 1909 in honour of Samuel Pierpont Langley, third secretary of the Smithsonian Institution, who was the first man in the world to make a large model heavier-than-air machine fly successfully under its own power, the medal has been awarded hitherto to four men: Wilbur and Orville Wright, Glenn H. Curtiss, and

Gustave Eiffel. Col Lindbergh stated that it has been decided to offer his machine, Spirit of St. Louis, to the Smithsonian Institution to be added to the collection of aeroplanes of historic interest that it possesses

The annual report of the Rockefeller Foundation for 1926 has recently been issued. During that year the Foundation expended 9,741,474 dollars on inedical research and the prevention of disease in all parts of the world. The activities of the Foundation are reviewed by the president, Dr George E Vincent, in this report, which is illustrated with relevant maps, charts, and photographs.

In connexion with the work of the Colorimetry Section of the U.S. Bureau of Standards and the report of the Colorimetry Committee of the Optical Society of America, Mr. Irwin G. Priest is desirous of compiling a bibliography of papers and books having a direct bearing on colorimetry, spectrophotometry, and colour specifications—It is expected that this bibliography will ultimately be published in the Journal of the Optical Society. He will be glad if authors who have contributed to this subject will send him check lists of their papers, giving titles and complete journal references. Reprints will also be of service and will be gratefully received—Mr. Priest's address is Bureau of Standards, Washington, D.C

MESSRS Gurney and Jackson will publish shortly "A Popular Handbook of Indian Birds," by H. Whistler, illustrated by many coloured and black-and-white plates and text figures by H. Gronvold

THE latest catalogue (No 503) of Messrs. Francis Edwards, Ltd., 83 High Street, Marylebone, W.1, although mainly of a general character, contains sections devoted to geography and travel, botany and gardening, entomology, folklore, and natural history. It should therefore be of interest to readers of NATURE.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned .—An assistant lecturer in agricultural chemistry at the East Anghan Institute of Agriculture, Chelmsford—The Clerk of the Essex County Council, Shire Hall, Chelmsford (Jan. 9). A science master for physics and chemistry at the Longton High School-The Director of Education, Town Hall, Hanley, Stoke-on-Trent (Jan 21). A reader in chemistry at Bedford College for Women—The Academic Registrar, University of London, South Kensington, S.W.7 (Feb. 17). rubber technologist to take charge of the rubber section of a government laboratory-The Commandant, Experimental Station, Porton, Wilts. lecturer in biology at the Saffron Walden Training College for Women Teachers—The Principal, Training College for Women Teachers, Saffron Walden.

#### Our Astronomical Column.

The Spectrum of the Comet Pons-Winnecke—Two papers on this subject have recently appeared. Dr. G. Shajn (Mon. Not. Roy Ast. Soc., Supp.) gives diagrams showing the changes in the relative strength of different bands. At the end of May the band at λ388 was the brightest, those at λ405 and λ469 being in order of lessening brightness. The first band remained stationary for a week and then got decidedly fainter; while the other two brightened, that at λ469 being the brightest at the end of June. The continuous spectrum was not visible at the end of May, but gradually grew in strength after this. There was more increase of light visually than photographically, implying a change of colour from blue to yellow.

Lowell Obs. Bull. No. 86 contains a discussion by V. M. Slipher of spectrograms obtained on June 20 and 23. The continuous spectrum was then strong and showed the solar absorption lines, indicating that the nucleus was shining by reflected sunlight. The Swan spectrum was weak; there were strong cyanogen bands at λ3883 and λ4216, but the strongest bands were an unidentified series between λ3993 and λ4075. The spray of light towards the sun was the most

emissive region.

This paper, like that of M. Baldet recently noticed in this column, directs attention to the remarkably small size of the stellar nucleus. The estimate at the Lowell Observatory gave a linear diameter of two or three miles, that of M. Baldet being less than a mile.

Measures of Double Stars.—Prof G. van Biesbroeck, in addition to his cometary work, undertakes a large amount of double-star observation with the 40-inch refractor at Yerkes Observatory. Vol 5, part 1, of its *Publications* contains his measures of some 3000 stars, the majority of which are stars the duplicity of which was discovered by Prof. Hussey

about the beginning of the century. The old and new measures are compared, and wherever sensible change appears an estimate is made of the hypothetical parallax, both on the assumption of a uniform mass double that of the sun, and also from the Eddington curve connecting mass with absolute magnitude. He also discusses the errors of published orbits and deduces many new ones.

One of the stars is the long-period variable X Ophruchi, which has an unchanging 8 9 mag. companion at a distance of  $\frac{1}{4}$ ". Its hypothetical parallax is 0".007, in good agreement with Adams's spectroscopic value 0" 005 from the unchanging component, the type of which is K0. It is noted that the trigonometrical measures published by van Maanen and Gringrich are probably affected by the apparent shift of the combined star-image due to the change in light. There is a new orbit given for \( \lambda \) Ophiuchi, rejecting the W. Herschel observations, which appear to be affected by some error. The period comes out as 150 The same period is suggested for 37 Pegasi, the orbit of which is turned edgewise to us. There are numerous observations of 70 Ophiuchi, Prof. van Biesbroeck thinks that the evidence for an unseen companion is not convincing.

The Schwassmann-Wachmann Nova—The Harvard storehouse of plates has once again proved of great service in tracing the behaviour of this Nova before its discovery. Miss Cannon publishes the following details in Harvard Announcement Card, No. 37. It was invisible (less than mag. 15) in plates of previous years; it first appears on Sept. 11 last, mag. 11·7; it rose to a maximum of 6 0 on Sept. 30; it had fallen to 7 4 on Oct 16, to 8·4 on Oct. 29, to 9 4 on Nov 19. Its spectrum was photographed with the 24-inch reflector on Nov. 20; the hydrogen lines were bright, the line at 4640 being five times as bright as Hs.

# Research Items.

THE MAORI PA. - Bulletin No. 6 of the Dominion Museum, New Zealand, is an elaborate account of the Maori pa or fort by Mr Elsdon Best, which, in addition to a generalised description of form, method of construction, and use, deals with a number of the old pas, though his list does not profess to be exhaustive. In no other part of Polynesia did the fortified village obtain to the extent it did in North Island of New Zealand, and although we hear of strongholds, of which those of Tonga most nearly resemble the Maori pa, nowhere do we find these used more or less permanently as they were in New Zealand. In various islands from the Philippines to Hawaii at intervals, some form of defensive work in stone, tunber, or earth is found; but the custom of living in these fortified villages seems to have been inherited from the first inhabitants of New Zealand, where, apparently, it was a very ancient institution. According to tradition, when Toi first reached New Zealand in the middle of the twelfth century, the Maori found the earlier peoples already using this form of defensive work, and they may have adopted it from them. It may have been spread to other parts by the inter-course between New Zealand and the other islands.

BIRD MALARIA. — The Department of Medical Zoology, School of Hygiene, Johns Hopkins University, is continuing, among other lines of work, the investigation of bird malaria. Dr. E. Hartman (Amer. Jour. Hyg., 7, No. 4, 1927) publishes the results of biometric studies on Plasmodium præcox in the canary. During the rise of the infection in the canary, the asexual forms of the parasite continue to die throughout the cycle The mortality rate is during 21 hours a mathematical constant, as determined by the fit of the data to an exponential curve. The finding of Mrs. Taliaferro was confirmed, that there is a constant rate of increase in numbers of the parasites from day to day until near the peak of the infection. Some cases show a constant rate of decrease of the number of parasites as the infection declines. The relapse cases show the same characteristics of constant rates of increase and of decrease as are exhibited by primary attacks. Relapses may be either more severe or more mild than the initial attack, but they are identical in type of infection. Relapse in bird malaria is usually milder than the primary attack. Symptoms in the bird follow sporulation and peak in numbers. Dr. Mary Stuart MacDougall (in the same journal, No. 5) presents a record of experiments indicating that the increase of the sugar content of the blood brings about a condition favourable for the parasite in bird malaria, and a decrease in the blood sugar by the use of insulin creates a condition unfavourable for the

Self-Fertilisation in Oligochætes.—[During investigations on Tubifex tubifex, L. Cernosvitov (Biol. Zentralbl., Bd. 47, p. 587, 1927) observed specimens in which the spermathecæ were absent. Such worms were, of course, incapable of receiving sperms during copulation. The presence or absence of spermathecæ or the presence of spermatophores in the spermathecæ is easily ascertained in T. tubifex, owing to the transparency of the body wall of the tenth segment in which the spermathecæ are situated. The proportion of worms without spermathecæ varies greatly. It is low (up to 6 per cent.) in collections made in localities where the worms are found in large masses and where the individuals are 8-10 cm. long, that is, under favourable conditions of

growth. In another locality where the worms did not exceed 3.5 cm in length, the percentage without spermathece reached 55 to 70, and in another collection of smaller worms all the specimens were abnormal. The author concludes that unfavourable conditions lead to anomalies in the reproductive apparatus. He isolated worms without spermathece and also worms which possessed spermathece, but in which no spermatophores were present, and in both cases the worms produced eggs which developed normally. Either self-fertilisation or parthenogenesis must therefore have occurred. As there was no difference in the number of chromosomes, he assumed that self-fertilisation had taken place, but in what manner was not ascertained. The author gives the number of chromosomes as not exceeding 76, as against the number 110 stated by Gathy.

Fishes of the Congo Basin.—In a recent report (Srtzungsberichte Akad. Wissensch. Wien, Band 136, Heft 5 and 6) M. Holly continues his descriptions of fishes collected by Dr. Haberer in 1907–8 in the southeast Cameroons. It contains the Siluridæ, Cyprinodontidæ, Acanthopterygii, and the Mastacembelidæ, taken in the Maka district which lies between the Bumba and Ja Rivers, both tributaries of the Congo. The collection has since lain in the Natural History Museum at Vienna. Four new siluriods and one new cichlid are recorded, fully described and figured. The author disagrees with Boulenger on some minor points in the descriptions of other species.

PLAGIOTROPISM.—This tendency of many plant organs to grow horizontally, or at a definite angle to the vertical, is regarded by W. Zimmermann as a 'plagiogeotropism.' He gives a very clear account of his recent experiments in Die Naturwissenschaften for Nov. 11, his original paper having appeared in the Jahrb. fur wiss. Bot., 66, 1927. Experimenting mainly with certain runners, such as those of the strawberry and Ranunculus repens, which can be grown fairly well in darkness, he shows that the position of the runner is determined by gravity, and that the angle to the vertical the runner assumes depends upon the algebraic sum of two internal (positive and negative) geotropic responses of the same organ. As these two opposite responses are not usually of equal strength and are not both at their maximum intensity when the organ is in the horizontal position, the result is a tendency to assume a definite angle in relation to the vertical, which is usually other than 90°, so that the organ grows at an angle to the horizontal. These views certainly seem to bring the phenomenon into line with the interpretation recently given by Gradmann in the same journal (Die Naturwissenschaften, April 15, 1927) of the movements of tendrils and the growth curvatures of twining stems. They do not carry us much farther forward until an interpretation is forthcoming of the internal mechanism of geotropic response.

Chromosome Linkage in Œnothera.—A significant paper dealing with the chromosome linkages which occur in many Œnotheras during diakinesis and the heterotypic mitosis, has been published by Miss F. M. L. Sheffield (Annals of Botany, vol. 41, p. 779). A very critical cytological study of several species and mutations shows a characteristic arrangement of the 14 chromosomes, except in one species in which the arrangement was variable. In two small-flowered species, Œ. novæ-scotiæ and Œ. eriensis, recently described from Canada, there is a closed ring of 14

chromosomes in diakinesis, followed by a regular zigzag arrangement on the spindle, thus determining the normal segregation of only two gametic types in pollen formation. Œ ammophila has one free pair of chromosomes and a ring of 12, while the mutation E. nubricalyx has four free pairs and a ring of 6. Only rarely do departures from these arrangements occur in a plant. The bearing of these important results on the further analysis of mutations in Œnothera is obvious It also appears that the linkage of chromosomes will account for the large amount of linkage of characters which occurs in Œnothera Various schemes of chromosomes interhybrids change and non-disjunction are worked out, in their bearing on the origin of mutations and other complicated problems in this group of plants.

FRUIT CANNING IN THE HOME.—Fruit canning as a home industry is at present almost unknown in England, one of the chief reasons being the difficulty for an unskilled operator to secure a satisfactory seal by soldering the 'hole and cap' can However, a new hand sealing machine, for use with the openended or 'sanitary' can, has been introduced and thoroughly tested at the Campden Research Station Full details for working this apparatus, with illustrations, are given in the Ministry of Agriculture's leaflet, No. 331. Although success depends chiefly on efficient sterilisation, the best results can only be obtained it the fruit for preserving is carefully selected for soundness and uniformity in ripeness. To avoid bleaching in the case of coloured fruit, cans coated with an acid-resisting lacquer can be obtained. Water gives quite satisfactory results as a covering liquid, but a sugar solution is better. The syrup, which must be used boiling, is poured over the fruit and the can sealed immediately, before cooling takes place, to ensure the exclusion of air. The cans are then boiled in water for sufficient time to destroy the enzymes and micro-organisms on the fruit, and finally cooled rapidly in running water to prevent over-cooking. The leaflet concludes with details of the best procedure to be followed in canning most of the common English fruits, as tested at the Research Station, together with a table indicating the best strength of syrup to use, and the time required in the boiling water to effect sterilisation in each case.

Forestry in British Honduras.—The annual report for the year ending Mar. 31, 1927, the fifth year of the Department's existence, has been recently issued. The final Forest Ordmance (Ord. No. 32 of 1926) became law on Oct. 14, 1926. Rules under the Ordinance were sanctioned in December and came into force on Jan. 1, 1927, thus providing for adequate protection of the forests and a stable system of forest finance. Under this Ordinance the contribution to forest trust funds from general revenue during the financial year amounted to 50 per cent. of the total general forest revenue, the balance required being met from the Forest Loan Department. A satisfactory feature of the organisation and management of the new Department is the close co-operation of the latter with the timber exploitation companies Substantial progress, it is said, has been made during the year in many aspects of the sylviculture of mahogany which will have, it is hoped, an appreciable effect in accelerating the establishment of a normal distribution of age classes over the areas in which improvements are being carried out. Arrangements are being made by the Chicle Development Company for intensive research to be carried out on their sapodilla estates in connexion with latex production and economic tapping methods This important work in conjunction with the reafforestation of sapodilla,

the investigations on the increment of Achras sanota. and the examination of the possible utilisation of interior grades of chiele gums from allied species, will have far-reaching effects on the reconstruction of the When it is remembered that the Ficus elastica was practically exterminated in the torests in the east of India by the seventies of last century through ruthless tapping, the steps being taken in the case of the sapodilla form a striking example of the manner in which public opinion is now commencing to envisage such matters Exploration is being commenced in the western highlands between Vaca and the Rio Grande. It is anticipated that the information concerning this little-known locality will be considerably augmented during the trigonometrical work to be carried out by the Survey Department in connexion with the demarcation of the western frontier.

IRRIGATION IN INDIA.—The irrigated area in British India, according to the report for 1925-26 ("Government of India · Department of Industries and Labour (Public Works Branch). Irrigation in India Review for 1925-26." Pp. 10+37 Simla Government of India Press), was 28 I million acres, or nearly a million acres more than in the previous year. The area is 129 per cent. of the total area cropped. In the Punjab the irrigation area was greatest; next came, in order, Madras, Sind, and the United Provinces. Among many projects now in progress to extend irrigation, the following are important The Cauvery Metur project to bring another 300,000 acres under irrigation; the Lloyd dam at Bhatgar in the Nira valley, and the Lloyd barrage at Sukkur on the Indus. The monsoon in India during the year under review was on the average 4 per cent below normal. It was characterised by strength in northern India until the middle of August, when it retreated abnormally early. In the Decean it was weak throughout the season The report contains statistical, including financial, details of the irrigation works in use.

Percolation in a Sandy Seashore. - The form of the surface of separation, under the ground near a sandy seashore, between the salt water which has diffused landwards from the sea, and the fresh water from the rain falling on the land, is investigated by T. Nomitsu, Y. Toyohara, and R. Kamimoto in No. 7, vol. 10 (Sept. 1927), of the Memorrs of the College of Science, Kyoto Imperial University. Herzberg, who had previously considered the problem, assumed that the fresh water was m statical equilibrium, floating on the sea water. The present writers take into account the seaward flow of the fresh water, and also the diffusion of salt into the fresh water underground. An approximate theory indicates that, as in Herzberg's theory, the surface of separation will be parabolic, but in the present theory the form of the parabola depends on the rate of flow of fresh water seawards, and on a certain constant of the soil. Diffusion of salt into fresh water is found to be relatively unimportant. Experiments on models confirmed the approximate theory.

Colloidal Solutions and Ore Deposition.—In recent years Dr. H. C. Boydell has suggested several important applications of the principles of physical chemistry to problems of ore deposition. He has now contributed to the Institution of Mining and Metallurgy a long and masterly presentation of the subject as he sees it. In his absence, the paper was read at the October ineeting by Dr. R. H. Rastall; it is published in the October Bulletin of the Institution. The chief topics dealt with are the processes involved in the precipitation of solids from molecular

and colloidal solutions. The abilities of colloidal solutions to account for many puzzling phenomena are summarised, and their many advantages over true solutions are convincingly recorded. Dr. Boydell missts, however, that he does not advocate colloidal influences to the exclusion of the agency of true solutions. The discussion that followed appears in the November Bulletin. Notable contributions, constructive and helpful in their criticism, were made by Prof J. W. Gregory and Prof. J. C Philip.

THE JAPANESE EARTHQUAKE OF MAR. 7, 1927.— Since the great earthquake of 1923, Japan has been visited by two destructive earthquakes, the Tazima earthquake of May 23, 1925, and the Tango earthquake of Mar. 7, 1927. The epicentres, which were only 11 miles apart, both he near the north coast of the main island and to the west of Wakasa Bay. Of the two, the later earthquake was much the stronger. It resulted, as we learn from a brief but very interesting report by Messrs A. Imamura and N. Nasu, in the loss of 2908 lives (*Proc. Imp. Acad. Tolyo*, vol. 3, pp. 227-231, 1927). Of the houses in the four central counties, 47 per cent. collapsed and 14 per cent were burned. Fault-displacements occurred along two old and independent faults. The Gô-mura fault, to the north, is 11 miles long, and runs N.N.W. and S.S.E., the west side being uplifted so much as 2 feet and shifted towards the south by nearly 9 feet. A short distance to the south of this fault is the Yamada fault, a little more than 4 miles long and running in a direction at right angles to the other Along this fault the north side has a maximum uplift of 16 inches and an easterly shift of 2½ feet. A permanent upheaval of about 21 feet occurred along the Japan Sea coast from the Gô-mura fault westward for about 10 or 12 miles. Soon after the earthquake, seismographs were erected at three stations near the epicentre. The after-shocks recorded belonged to two Those originating near the Yamada fault were of shallow origin, the foci in no case being more than 5 miles deep, while the others, belonging to the Gô-mura fault, originated in foci that were sometimes 121 miles in depth.

TERRESTRIAL MAGNETISM AT SAMOA.—The Apia Observatory, Samoa, was founded in 1902 by the Gottingen Academy, originally for three years, and later as a permanent institution. When Samoa was occupied by New Zealand troops in 1914, the observatory was taken over by the N.Z. Government; the German director, Dr. G. Angenheister, with a staff of assistants, remained in charge until 1920, when arrangements for the further maintenance of the observatory were concluded between the N.Z. Government, the British Admiralty, and the Carnegie Institution of Washington. Dr. Angenheister was succeeded by Mr. C. J. Westland as acting director, and afterwards by the present director, Dr. Andrew Thomson. The reports of the observatory under the new regime have been issued for the years 1921 to 1923 (the last appearing in 1926), giving hourly values of the magnetic elements, and summaries of the observations on meteorology, seismology, and atmospheric electricity. Under arrangements with the New Zealand Government, Dr. Angenheister took with him on his return to Germany the observations taken under his direction, in order that he might reduce and discuss them. A summary of these data for the years 1912-1920, so far as they relate to terrestrial magnetism, has recently been issued, under the editorship of Prof. D. M Y. Sommerville, of Wellington College, N.Z. It is to be hoped that this valuable summary will later be supplemented by the publication of the actual hourly values. The observations at Samoa are of particular importance, owing to the extreme paucity of magnetic observatories in the southern hemisphere, and to the great distance of Apia from the next nearest observatory. The value of the data is naturally enhanced by the now considerable period over which observations have been made there.

Rubber Sulphur Compounds—Paper No. 560, by Curtis, McPheison, and Scott, published by the U.S. Bureau of Standards, gives the density and electrical properties of the compounds of rubber and sulphur for the range of composition from 0 to 32 per cent. of sulphur, that is, from crude rubber to hard lubber. Important changes in the properties with the proportion of sulphur are noted. These changes show definite regularities and occur at compositions which may be represented by simple empirical formulæ The authors conclude that this indicates the existence of definite compounds of rubber When the composition contains 19 per and sulphur cent. of sulphur, all the properties that were studied undergo significant changes. At this composition the slope of the curve connecting density with percentage of sulphur changes; so also does the curve showing the thermal expansion to percentage of sulphur Both the specific inductive capacity and the power factor curves pass through minimum values at 19 per cent. of sulphur, while the resistivity curve bends The specific inductive capacity has a very upwards decided maximum value when the composition is 105 per cent of sulphur. The power factor shows a maximum at 13 5 per cent, whilst the resistivity does not attain its maximum value until the percentage is Experiment showed that the effect of free sulphur on the electrical properties was small compared with the effect of the combined sulphur. Electric strength measurements are not recorded, because it was found that they seemed to be affected more by the conditions of the test than by the properties of the compound

THE ATTENUATION OF RADIO WAVES OVER LAND.— Mr R H. Barfield read an important paper on Dec 7 at the Institution of Electrical Engineers on the attenuation of radio waves when passing over land. The intensity of the London broadcasting station  $(2LO; \lambda = 364 \text{ m.})$  was measured in seven different radial directions, up to distances of about 100 miles. The over-all attenuation coefficient was then found from the experimental results and compared with results obtained by Sommerfeld's theory. The numbers found experimentally were much greater than the theoretical numbers. It is suggested that this discrepancy can be explained by the well-wooded nature of the English countryside. The energyabsorbing property of individual English trees was measured experimentally, and calculations are made for given densities of tree distribution founded on these results. It is concluded that the greater part of the discrepancy between theory and experiment can be ascribed to the trees. The experimental results show no evidence of screening or other effects produced by hills. The directions investigated included routes over the North and South Downs and the Chiltern and Cotswold ranges. It is proved that about 1600 trees per square kilometre will have an attenuating effect equal to that of the earth in the given experiments. In particular, actual counts in the districts north of London give 500 trees per square kilometre, and in the districts south of London about 4000 trees per square kilometre. Calculations based on the latter number give the observed value to the attenuation coefficient, but the agreement with the north of London routes is not good. Probably hedges and other vegetation, houses and other erections, contribute to the absorption produced

# The Hungarian Biological Research Institute.

By Dr. F. A. BATHER, F.R S

ON Sept. 5 the Regent of Hungary, Admiral Horthy, inaugurated the new buildings of the Hungarian institute for biological research at Tihany on the shores of Lake Balaton (Fig. 1). This institute has been founded through the exertions of the Minister for Education. Count Kuno von Klebelsberg, in pursuance of the general policy of the Government to restore the various cultural institutions of Hungary to the same high level as they occupied before the War, and where possible to raise the standard. It is gratifying to note the importance which His Excellence has attached to the development of the natural sciences. During his term of office one new university has been founded, and two rendered homeless as a consequence of the War have been re-established

of an age ranging from Miocene to Permian. This is particularly the case at Tihany, where Eocene rocks capped by basaltic tuff form a peninsula which stretches more than three-quarters of the way across the lake. On the summit of the cliff stands the Benedictine abbey, founded in 1054, and on the strip of shore at its foot, between a small hotel and a villa of the Archduke Joseph, is the site of the research institute, enlarged to about four acres by building out on the shallow sandy lake floor. This site will be occupied by four main blocks. the laboratory building, lodgings for visiting workers, residence of the staff, and an aquarium open to the public, only the first two are completed.

The laboratory building consists of basement,

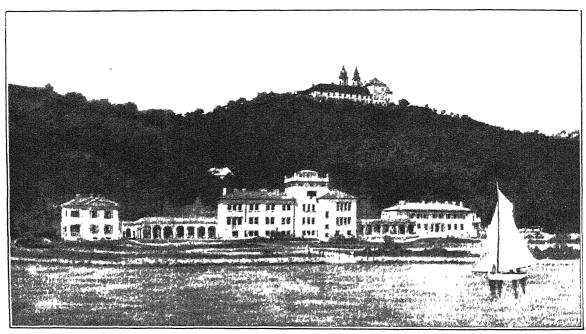

Fig. 1.—Hungarian Institute for Biological Research, Tihany, Lake Balaton.

in fresh situations. Among the new developments may be mentioned the excellent modern equipment of the medical faculty at Debrecen, but the support accorded to pure biological research through this institute at Tihany is a still more manifest sign of this enlightened policy.

The present institute was founded in 1926 in continuation and development of the Biological Station which was maintained at Révfulop by the Hungarian National Museum. Work will continue in co-operation with other laboratories in Hungary, but the new situation and the admirable arrangements will greatly facilitate research.

Lake Balaton is the largest piece of fresh water in the south of Europe. With a length of 51 miles, it varies in width from two to nine miles, and attains in places a depth of 425 feet. It is rich in fishes and other forms of life. While the southern shores are low and flat, those on the north are formed by picturesque hills sloping steeply to the water. These hills owe their existence to a capping of Phocene basalt and other volcame rocks, which have preserved from complete erosion the underlying softer rocks,

raised ground floor, first storey, and a tower which adds another storey, and a flat roof with a small room on it. The institute is organised in two departments. The first, which occupies the ground floor, and is immediately under Dr. Béla Hankó, administrative director of the Institute, is devoted to zoology, botany, and hydrobiology. It contains the reception room and the laboratory of the director, the library, a laboratory for the botanist, one for the bacteriologist, a microscopical laboratory with six tables, and a room for the laboratory assistants.

The second department, which is on the first floor, conducts physiological, physical, and chemical research, and is directed by Dr. F. Verzár of Debrecen It contains the laboratory of the director of the physiological assistant and a laboratory for the official chemist, two laboratories for single research workers, a balance-room, and an assistants' room. There is also a large laboratory for demonstrations to twenty students.

The tower contains an optical room, a drawing and photographic room, with a dark room, and the cisterns for Balaton water and artificial sea-water.

On the roof will be placed meteorological instruments. In the basement are workshops, store-rooms, engine rooms, and mechanician's lodging, a cold aquarium, fish-breeding plant, and a room protected against tremors by special pillars, and thus permitting of the finest physical measurements and photographic work

Each working-place has a double aquarium with flowing Balaton water and aeration, a supply of three kinds of electric current, of gas made in the institute from benzol, of compressed air and vacuum draught, and of drinking water, and a hot-water heating apparatus. Water is sucked from a point 200 metres out in the lake, through a pipe of eternite into three successive basins, where the sediments settle, and is then sent by a bronze centrifugal pump to the cisterns in the tower; these last are painted with innertol, and the water supply pipes in the building are of lead The working aquaria are modified from the Naples model, three of them can receive artificial or actual sea-water, which is stored ın a stone cıstern.

The thermostats, kymograph, nephelometer, and colorimeter, lighting, photographic, and all other apparatus are of the very latest and best design

m whatever country that could be found The lodgings in the adjoining block provide twenty-six beds, in fifteen rooms; these are at present partly occupied by the staff There are also a dining-room, servants' bedrooms, and the usual offices.

The programme of the Institute is, first, the biological investigation of Lake Balaton and other Hungarian waters; but it will undertake all kinds of research in general biology and physiology for which its resources are adapted. At certain times educational courses will be conducted, especially for teachers in secondary schools. It is particularly hoped that foreign workers will avail themselves of the facilities offered Tables will be allotted to them according to the available room. A monthly fee of 125 penzo (about 14s. 4d) covers a fitted working place, lodging, and research material up to 25 penzo (say 3s.). A place can only be retained so long as it is really used for work. His Excellence the Minister of Education expressed to me the wish that it might be possible to arrange for an exchange of similar facilities between Tihany and similar laboratories in the British Dominions at home or overseas, he would also be glad to see an exchange of publications. Should the publication of this appeal in Nature meet the eyes of the very variously constituted bodies that govern such institutions within the British Commonwealth, they will doubtless respond to it in a friendly spirit. Those who wish to have complete sets of the Annals and other publications of the institute should not wait until the earlier numbers are out of print. Correspondence may be addressed to the Director, Dr. Hankó, Magyar Biológiai Kutato Intézet, Tihany, Balaton, Hungary.

# The Undercooling of Some Aluminium Alloys.

ALTHOUGH the undercooling of pure metals was observed by Roberts-Austen so long ago as 1898, no experimental data have so far been published regarding the supersolubility curves of alloy systems, although explanations of certain structures have been based on their existence particularly in regard to The recent May Lecture of Sir Henry

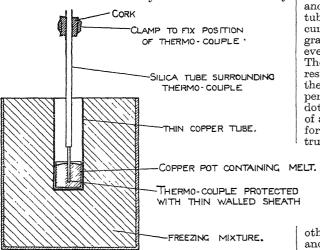

Fig 1.—Diagram of apparatus

Miers to the Institute of Metals on "The Growth of Crystals in Supersaturated Liquids" is now followed by a paper by Dr. Marie L. V. Gayler, delivered before the Institute of Metals on Sept. 7, on the effects of undercooling in some alloys of aluminium, in par-ticular with silicon. The work was carried out for the Engineering Research Board at the National Physical Laboratory under the supervision of Dr. W. Rosenhain and breaks entirely new ground. For the first time the supersolubility curves for an alloy system are available, and with their aid an explanation of the structures of the aluminium-silicon alloys can be offered with a considerable degree of certainty.

The experimental method adopted consisted in melting the alloy in a thin copper pot, the wall thickness of which did not exceed  $\vec{r}_1$ , in , raising the melt to a temperature of about 200° C. above the liquidus and then quickly dropping the pot into a copper tube immersed in a freezing mixture. A cooling curve was obtained on a Rosenham plotting chronograph, readings being taken every 10° C. at first and every 5° C after the first arrest had taken place. The general arrangement is shown in Fig I <sup>1</sup> The results are represented by the dotted lines in Fig. 2, the continuous lines in the latter indicating the temperatures of the changes as normally accepted. The dotted lines indicated in Fig. 2 are thus representative of a definite rate of cooling, but there are good reasons for the belief that they approximate closely to the

true supersolubility curves. In the first place, as will be shown later, they offer good grounds for the mterpretation of the microstructure observed in the ingots, but far stronger reasons for this

belief lie in the following facts.

As is well known, the aluminium-silicon alloys are normally more or less brittle. When, however, to the melt is added a small trace of sodium or other 'modifying' material, their mechanical properties and structures are radically effected. If the 'modification' is due to crystallisation along the supersolubility curves, it should follow that the freezing curves after modification should at any rate approximately coincide with the latter curves themselves. Secondly, the 'modification' should inhibit the attainment of a second series of supersolubility curves lying below those previously obtained. Miss Gayler has shown that both these results can be obtained. The freezing diagram obtained from the 'modified' alloys lies remarkably near to that of the supersolubility curves in Fig. 2, and systematic under-

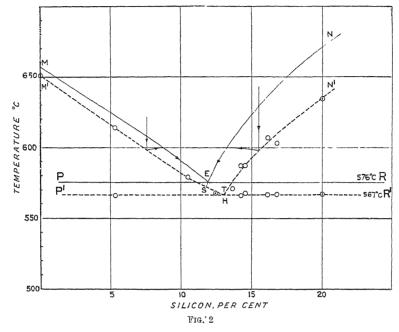

<sup>1</sup> This and other illustrations are reproduced by courtesy of the Institute of Metals

No. 3035, Vol. 1207

cooling does not occur in the 'modified' alloys, supersolubility curves for which could, therefore, not be obtained.

The correlation of the foregoing curves with the microstructures is excellently effected. In Fig 3, it

structure of which is shown in Figs 4 and 5, however. silicon separates first at some point on the supersolubility curve N'II The composition of the liquid then follows NS until S is reached, when aluminum separates spontaneously; the course of the liquid

will be seen that besides the primary dendrites of aluminium, coarse silicon is present; this suggests that in this alloy, containing 10 per cent. of silicon, aluminium separates on cooling at a point on the super-solubility curve M'H in Fig. 2. The composition of

then probably oscillates between SH and TH until the point H is reached, when aluminium and silicon separate together It will be seen in Fig. 5 that the primary silicon is surrounded by dendritic aluminium. The structures of the ingots obtained are of much

Fig 3.-100 per cent silicon. Centre of ingot

the liquid then follows MET until the silicon supersolubility curve is reached at T, when silicon separates along TH until the hypertectic point H is reached and both constituents separate simultaneously. In the alloy containing 13.2 per cent. of silicon, the

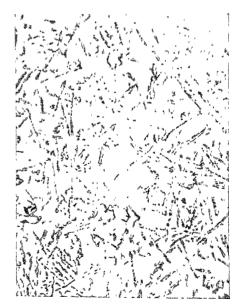

Fig. 4-13.2 per cent. silicon Edge of ingot.

interest, and the results may not improbably throw considerable light on the general question of ingot crystallisation. Contrary to what would, perhaps, generally be expected, since the outside of the ingot must be the more rapidly cooled, the structure of the

No. 3035, Vol. 1201

outside rim to a depth of approximately 1. in is much coarser than that inside. The character of the crystals is also different, particularly that of the silicon,

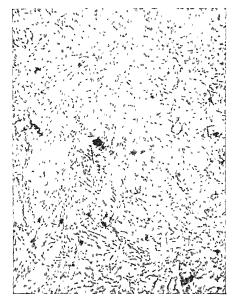

Fig 5-13 2 per cent silicon Centre of ingot ×150

which takes a definitely needle shape, while the silicon in the centre of the ingot is in more rounded particles and much finer needles. F. C. T.

# University and Educational Intelligence.

LONDON.—The title of emeritus professor of pathology in the University has been conferred on Sir Frederick Andrewes, who retired from the University professorship of pathology tenable at St. Bartholomew's Hospital Medical College in July last.

The Senate has decided to make a grant of £200 a year for five years towards the cost of maintaining the British Institute in Paris.

The following doctorates have been conferred: D.Sc. in Chemistry—Miss P. V. M'Kie (Bedford College), for a thesis entitled "The Interaction between Nitric Acid and Unsaturated Compounds", and Mr. A. W. Chapman (Imperial College (Royal College of Science)), for a thesis entitled "Studies of Isomeric Change—with special reference to the Molecular Rearrangement of Immo-aryl Ethers." D.Sc. in Zoology—Miss H. S. Pearson (University College), for a thesis entitled "On the Skulls of Early Tertiary Suidæ, together with an Account of the Otic Region in some other Primitive Artiodactyla." D.Sc. in Veterinary Pathology—Mr. F. C. Minett, for a thesis entitled "The Standardisation of Immune Serum and the Nature of Immunity in Foot and Mouth Disease," and other papers.

A free public lecture on "Recent Discoveries throwing New Light on some of the Commonest Insects" is to be given by Prof. E. B. Poulton, at Bedford College for Women, at 5.15 on Jan. 31.

With the view of encouraging original research in sanitary science, the Grocers' Company is offering scholarships of the annual value of £300 each, plus a further amount for expenses. The scholarships are tenable for one year, but renewable up to three years. A form of application can be obtained from the clerk of the Grocers' Company, Grocers' Hall, E.C.2.

The Pan-American Union has issued in Washington, D.C., two pamphlets containing the projects of the International Commission of Jurists, "Public International Law" (pp. 40), and "Private International Law" (pp. 68). These drafts are the findings of sessions held at Rio de Janeiro in April and May 1927, and are to be submitted for the consideration of the sixth International Conference of American States which will convene at Havana, Cuba, in January 1928. Under Public International Law two of the earlier projects are (v) Exchange of publications and (vi) exchange of professors shall be paid by the institution which has appointed him, unless his services shall have been expressly requested, in which case his remuneration shall be borne by the institution which invited him. In Private International Law, Chap, it is on domicile: "The domicile of diplomatic officials and that of individuals temporarily residing abroad in the employment or commission of their government or for scientific or artistic studies, shall be the last that they had in their own territory."

The annual meeting of the Science Masters' Association will be held on Jan. 4-6 at the Imperial College of Science, under the presidency of Sir Richard Gregory. Evening meetings will be held at King's College for Women, Campden Hill Road, Kensington, W.8, where the presidential address on "Contacts of Science and Literature" will be delivered on Jan. 4 The programme includes discussions on the nced of scientific investigators for the agricultural industries overseas, to be opened by Sir J. B. Farmer and Capt Irby (Colonial Office), and on industrial openings in scientific technology, to be opened by Prof. W. A Bone, and lectures by Dr. J. W. T. Walsh on modern methods in photometry and by Prof. J. C. Philip on charcoal and its activation. Visits have been arranged to the London docks, the United Dairies, Ltd., the Lighting Service Bureau, the Gas, Light, and Coke Co., and to the new laboratories at Highgate School. During the meeting there will be exhibits by members of the Association and by instrument makers and related firms, and also a display of books by leading publishers. Correspondence should be addressed to the organising secretary, Mr. I. M. Bankes-Williams, at the Chemistry Department, Imperial College of Science, South Kensington, S.W.7.

THE October number of the University Bulletin, issued by the Association of University Teachers, contains a report on the representation of teaching staffs upon university bodies. This is the outcome of the labours of a committee appointed to inquire into the subject. A sufficient warrant for undertaking such an inquiry is to be found in the University Grants Committee's report of 1925, in which attention was directed to the reasons why lecturers as well as professors should be accorded a more clearly recognised position in the government of the universities, and, in particular, why they should be represented on the executive governing bodies. Appended to the report of the Association's committee, which concludes by reaffirming the opinions of the University Grants Committee, is a useful tabular statement showing the actual position in the civic universities of England and the University of Wales In the same number appears, under the title "Jottings from the University of Utopia," a summary of advanced views on adult education, vocational guidance, and "earning while learning." In an article on the "wider aspects of extra-mural work." emphasis is laid on the value to the civic universities of their adult education work as a means of keeping them in touch with public opinion in the regions they serve.

#### Calendar of Customs and Festivals.

January I.

FEAST OF THE CIRCUMCISION -New Year's Day. marked in the Christian Calendar as the Feast of the Circumcision, being the eighth day after the day fixed by the early Church as the birthday of Christ, which coincides with the great mid-winter festivals of paganism The ceremony of circumcision, usually, though not invariably, a puberty or initiatory ceremony among races practising the rite, was performed by the Jews on the eighth day after birth. Circumcision was an essential condition of participation in the Passover and was enjoined on every male member of each household, including slaves, and on proselytes. In the case of the latter, however, it became later a subject of acute controversy. A widespread custom among modern peoples, especially in Africa, its origin and purpose are obscure. It was practised by the ancient Egyptians, but probably was not originally a Hebrew or even a Semitic rite, although the use of a stone to circumcise the son of Moses, as is usual when an obsolete instrument or material is used ceremonially, is an indication of high antiquity. attribution of its practice to Abraham may be taken as a mythical explanation of its significance in Jewish ritual as a mark of the right of admission to or a condition of participation in the most important of Hebrew ceremonial observances.

NEW YEAR'S DAY.—Although the entry upon a New Year has not always and everywhere taken place upon Jan. 1, its proximity to the winter solstice. when the sun turns to an upward path, made this a peculiarly acceptable date to peoples of the northern hemisphere, where there is a marked difference between winter and summer. Among other seasons which have served for the beginning of a new annual period are early spring or late autumn, at about the time of what is now All Souls, coinciding respectively with the awakening and the closing of the activity of vegetation—the turning points of the Celtic year the rising of the Pleiades or the end of the harvest. while the ancient Egyptians, in theory, regulated their

year by the heliacal rising of Sirius.

Whatever the period of the year adopted, the practice common to many peoples is to prepare for the new era as the old year draws to a close by a period of ceremonial purification which drives out evils and especially the spirits and ghosts of the dead, this being followed by a time of rejoicing, just as in the English Church the peal of bells welcomes the New Year after the solemn vigil of the Watch Night. In the Andamans at the end of the monsoon, the spirits which haunt the village are collected in leaves which are thrown into the sea The pagan tribes of Borneo send the spirits of evil floating away in little boats.

In Great Britain there are still traces of this desire to be rid of the influences of the past. Sometimes old clothes are burned on New Year's Eve. New clothes, or at least some one piece of new clothing, must be worn or no good luck will follow. A significant custom of the Strathdown Highlander in Scotland enjoined the drinking of water from the "dead and living ford," an aspersion, and a fire of jumper branches gathered for the purpose on New Year's Eve and put to dry all night, which made a stifling smoke in all the house, as a necessary preparation for the rejoicings of New Year's Day. Horses and cattle were also fumigated.

Many primitive peoples practise the ceremony of the scape-goat at the New Year, the sins and ills of the community being borne away by the animal, goat or other, when it is driven out. Possibly the same idea lies far behind the custom once followed in

Cumberland and Westmoreland of riding on the stang,' a piece of timber, all who refused to contribute to the merrymaking expenses of the party

carrying the stang.

Most modern New Year's customs, while involving the element of merrymaking, in their relation to belief-religious in a broad anthropological senseare originally connected with omens, forecasting fortune in the coming year, the omen becoming, as often, by intentional performance an ensurance of good luck. A man, not a woman, and dark and not fair, should be the first to cross the threshold on New Year's morning. Something should be brought into the house, even if only a piece of coal, before anything is taken out; some new garment should be worn. Hence the custom of 'first footing'—the house-tohouse visits after twelve o'clock of parties headed by a dark man bearing food and drink, thus ensuring prosperity to the house during the coming year custom of New Year gifts, now more common perhaps on the Continent than in England, goes back to the Romans and beyond—a custom in which the early Christians were forbidden to join. The ceremonial cutting and distribution of the mistletoe by the Druids in the New Year, a practice now transferred to Christmas, was intended to ensure the same prosperity among the worshippers throughout the year.

EPIPHANY. TWELFTH NIGHT. OLD CHRISTMAS DAY. Twelfth Night marks the end of the celebration of the Christmas or winter festival, though there is evidence for a period of twenty days which was sometimes prolonged until Candlemas It is especially associated with honour to the Three Magi or kings who brought gifts to our Lord, in memory of whom royalty used to make offerings of gold, frankincense,

or myrrh on this day

The customs of Twelfth Night fall into at least three groups. The best known were connected with the feast, with a regular ceremonial, which for long was observed by all from royalty downward in England, France, Germany, and other countries, though when celebrated by Mary Queen of Scots it was recorded as a French custom. This ceremonial included the election of a king, known as the 'King of the Bean,' and sometimes a queen, and a ceremonial cutting of the Twelfth Night cake, in which was included a bean or com, allotting the office of king, and sometimes other gifts, foretelling varying fortune for those who obtained them. In Herefordshire a holed cake was made which was placed on the horn of an ox in the stable, and according as he tossed it in the direction of the bailiff or the mistress, it became the perquisite of either.

The election of a king or 'Lord of Misrule' points

to that frequent subversion of law and order in certain types of festival such as the Saturnalia and the Carnival, which derives from the primitive abandonment of all social regulation and the prevalence of complete sexual licence at certain stated seasons for the magical promotion of fertility in Nature. In the west of England it was the custom to light fires in the fields or on the hill tops. In Gloucestershire thirteen fires represented our Lord and the twelve apostles, and in Brough in Westmoreland holly bushes with torches attached were carried round the town. These customs are comparable with the ceremonial bonfires at midsummer and other times of the year.

A fertility ceremonial is also recorded. In Cornwall, Devon, and Herefordshire, it was the custom to visit the orchard, and after firing a gun, which would drive away the spirits of evil, to pour a libation of cider over the apple trees, while a verse—a charm to secure a good crop-was recited.

#### LONDON.

Linnean Society, Dec. 1—A T Hopwood: Exhibition of vertebrate remains from the Miocene of Kenya Colony. These specimens are the first mammals from beds older than the very top of the Phocene recorded from the eastern half of Central Africa. The collection contains three genera of creodonts, two of artiodactyls, and three or four of rodents containing some seven or eight species. The rodents are closely allied to those living in the region at the present day.

Society of Public Analysts, Dec 7 -Harold Toms . Oil bromine films and their use in determining the halogen absorption of oils Oil films exposed to an atmosphere of bromine absorb the halogen quantitatively, and, after removal of the excess of bromine at a low temperature, the bromine absorption can be determined gravimetrically. The method, which gives accurate results with 20-50 mgm of an oil, has been used to determine the composition of the insoluble bromide of linseed oil, after removal of the bromine, by prolonged treatment with nascent hydrogen. The iodine values, calculated from the bromine absorbed. agree with those obtained by the Wijs method, except in the case of tung oil, the gravimetric bromine absorption of which stands in a constant relationship to the rodine value -G. Middleton and F. C. Hymas. Tests for impurities in ether. (1) Tests for peroxides Only organic peroxide (probably dihydroxydiethyl peroxide) is to be expected in ether purified for anæsthesia. The ferrous thiocyanate test is recommended for official adoption, and a colorimetric limit for the amount of peroxide is proposed gives no coloration with pure ether, and is not too stringent for practical purposes —H. J. Stern: Arsenic in coated papers and boards. Mineral pigments are usually satisfactory, but some of the synthetic in-organic pigments may be dangerous. Thus, a paper coated with an arsenical green may contain more than 6 gm. of arsenious oxide per square metre Some of the lakes of synthetic dyes, notably magenta and methyl violet, precipitated with arsenious oxide, contain dangerous amounts of arsenic (e g 40 5 per cent. of As<sub>2</sub>O<sub>3</sub>). Certain dyes, notably Pigment Scarlet 3B and Orange II, may contain 50 to 100 parts of arsenic per million. A provisional arrangement is in force limiting the amount of arsenic to 10 parts per million, and the boards in use seldom contain more than 2 or 3 parts per million.

#### CAMBRIDGE.

Philosophical Society, Nov. 21.—D. R. Hartree: The wave mechanics for an atom with a non-Coulomb central field. The methods developed can be applied to find the self-consistent field of an atom, that is, a field such that the solutions of the wave equation for that field which corresponds to core electrons give a distribution of charge which reproduces the field. Approximations to the self-consistent fields for He, Rb<sup>+</sup>, Na<sup>+</sup>, Cl<sup>-</sup> have been worked out; for the normal state of He the characteristic value of the wave equation for the self-consistent field gives an ionisation potential of 24.85 volts (obs. 24.6 volts), the most extensive work is for Rb, for which the general agreement between calculated characteristic values and observed terms of optical and X-ray spectra is satisfactory.—W. H. McCrea: The specific heat of hydrogen at high temperatures. The specific heat of hydrogen calculated from the empirical energy levels found by T. Hori from the H<sub>2</sub> band spectrum is in good agreement with experiment,

especially for temperatures in the neighbourhood of 2000° abs. Similar calculations for oxygen, nitrogen, and carbon monoxide do not give agreement with observed values.—S. L. Malurkar. On the arc spectrum of antimony. The arc spectrum of antimony has been arranged as due to the combination of about thirty levels which are denoted by  $3d_2d_1$ , 1s,  $3D_2D_1$  and Greek letters by Ruark-Mohler, Foote, and Chenault. It was possible to fix approximately the nature of these levels after the Hund-Heissenberg theory of complicated spectra. A note is added on the arc spectrum of arsenic

#### DUBLIN

maintenance requirements of cattle on different rations and at different rates of production; with a note on 'dynamic action.'"—J Wilson The maintenance requirements of cattle A reply to E B. Forbes's criticism.—D. T. Barry and J. Freud. Some experiments on feeding rats with soya bean and other materials Feeding white rats on soya bean and its products causes some diarrhea, but no avitaminosis is noted as compared with meat On white flour alone, avitaminosis was evident and also protein deficiency in one case by the animal eating its tail. This was corrected by meat. Soya products are good supplementary foodstuffs.—E. T. S. Walton: The formation of vortices behind a cylinder moving through a fluid. A large number of photographs have been taken of the vortex trains behind different cylindrical rods moving through water at various constant velocities, the drag on the rod being also recorded in each case. The experiments were undertaken to test Kármán's formula for resistance  $R = \rho h h / \tau$  and the modified formula of Synge, involving an additional term. The velocity of the vortices was found to be u=0.146U, which is about one-third of the value obtained on Kármán's assumption  $\kappa = Ul$ . For large Reynolds's number the resistance was found to agree approximately with Kármán's formula, when the values obtained by experiment were substituted on both sides of the equation. The additional term in Synge's formula was less than the experimental error. Graphs are given connecting the dimensionless quantities  $D/U\tau$ , u/U,  $R/\rho DU^2$ ,  $\iota/lU$  with the Reynolds's number —J Bayley Butler and J. J. C. Buckley. Catenaria anguillulæ as a parasite of the ova of Fasciola hepatica The infection arose in some ova of the fluke that had been kept in the laboratory nearly nine months, and is believed to have been introduced through changing the water in the testtubes. The cultures are readily grown on living and dead ova, and a large percentage of eggs exposed to infection become infected within a week. The development of the zoospore, the formation of sporangia and the re-infection of other eggs by zoospores, were described.

#### LEEDS

Philosophical and Literary Society, Nov. 15.—W. F. Beard: On the occurrence of a determinantal system of points of the fourth order.—F. A. Long: An electromagnet giving large fields. An electromagnet is described which gives considerable fields in a wide gap with small power consumption. It includes an oil-cooling and insulating system and a device to prevent a large E.M.F. developing on breaking or changing the current.—D. Brown: Further experiments on electron reflection. An account of an investigation into the energy of low-speed electrons after striking hot and cold oxide surfaces. The results suggest that whereas a hot oxide surface

behaves like an ordinary good conductor, the cold surface, by reason of its semi-insulating character, becomes electrically charged, thus influencing the energy of the reflected electrons—E. W. Smith: The oxidation of branched chain aliphatic acids. The results indicate an increasing ease of oxidation in the series isobutyric, isovaleric, isocaproic, isoheptylic These qualitative experiments were carried out chiefly to explore the suitability of this series of acids for definite measurements of their initial velocity of oxidation -H. M Dawson. The coordination of the catalytic effects produced by an acid in different reactions and a modified form of the generalised catalytic equation. An alternative form of the general equation which co-ordinates the catalytic effects of hydrogen ion and acid has been derived. The ratio of the quantities of salt which are required to reduce the reaction velocities of two different reactions to their respective minimum values depends on the square root of the ratio  $k_h/k_a$ For a given catalysing acid this salt ratio is independent of the concentration of the acid.-J H. Priestley and Dorothy Tong · The effect of gravity upon cambial activity in trees Gravity modifies the activity of the cambium in horizontal woody stems. In the Dicotyledon it increases wood formation and retards lignification on the upper side of the stem and decreases wood formation and accelerates lignification on the lower side. There are numerous exceptions to this rule in Nature. In the Gymnosperm the effect of gravity is to produce more wood with thicker walls and greater lignification on the lower side. There are very few exceptions to this rule. That in all cases lignification and the thickening of the wall proceeds more quickly on the lower side of the branch. explains the fact that on this side the wood elements are shorter and therefore better able to resist compression, while the longer elements on the upper side resist tension better. The different behaviour of Dicotyledons and Gymnosperms is correlated with other differences in cambial activity in these two groups.

#### Paris

Academy of Sciences, Nov. 28 .- V. Grignard and G Mingasson: The reduction of acid chlorides under reduced pressure: method of preparation of aldehydes. With nickel or nickel chloride as catalyst, at a temperature of 225° C. hydrogen at a pressure of 140 mm. reduces benzoyl chloride to benzaldehyde, with a yield of 60 per cent. At 200° C, with hydrogen under 400 mm., phenylacetyl chloride gives a 50 per cent. yield of the aldehyde. The chlorides of fatty acids under similar conditions also give aldehydes, but the yields are poor, probably owing to the higher vapour pressures of the aldehydes produced. #### GENEVA.

Society of Physics and Natural History, Oct 20.-Fernand Chodat: Results of an atmometric inquiry at the "La Linnæa" alpine garden. The author communicates results of the application of atmometric methods to plant ecology. The experiments clearly show that with a new quantitative index, the atmometric index (numerical value of the evaporation of the place studied), it is possible to complete the ecological description of a plant station.—Raoul Pictet: Experimental demonstration of the potential of the ether. Its consequences in the physical theory of the properties of vapours and gases. In support of his theory on the reality of the ether, the author indicates an experimental scheine which would tend to confirm the results described in a previous note. Arthur Schidlof: The interpretation of the masses of the electron and the proton in the universe of five dimensions. Keeping all the other premises of the theory of the five-dimension universe of O. Klein, but relinquishing the supposition that the Einstein element of space-time ds is an invariant, a unique equation is obtained for the electron and proton which allows an interpretation of the fact that the change of sign of the electric charge gives as a consequence a value of the true mass of the proton 1840 times as great as that of the electron.

#### ROME.

Royal National Academy of the Lincei: Communications received during the vacation.—U. Cisotti: The divergence of tensors.—G. Abetti: Observations of the partial solar eclipse of June 29, 1927, carried out al,

Arcetri — A. Angeli · The biochemical transformation of tyrosine into pyrrole derivatives Tyrosine is convertible into pyrrole derivatives by the action of oxidising enzymes and into 5 6-dihydroxymdole by means of tyrosmase, and Bloch suggests that the melanins are formed from hydroxytyrosine under the influence of a special enzyme, termed dopa-oxydase Since, however, hydroxytyrosine has not yet been detected in the animal organism, and extracts of melanotic tumours do not colour tyrosine, although they readily blacken with pyrrole, it seems probable that, in such cases, the formation of melanin is due to the less complicated oxidation of products containing ready-formed pyrrole nuclei in their molecules —G Lampariello: The theorem of the derivation by series -B. Colombo. The transformations (m, n) between m+n+4 integrals of two equations to the partial derivatives of the second order in two independent variables -- A Colacevich. Estimates of the magnitude of the Pons-Winnecke comet. Naked-eve, binocular, and equatorial observations of this comet made in June give for its magnitude values varying from 4.7 to 9.3 The nucleus appeared to be stellar, especially during the period June 20-26. Indications of a tail were discernible by means of the equatorial, the length from the nucleus being 8' The head appeared as a circular nebulosity of radius 4'—L. Fernandes Complexes of uranyl with polyphenolic acids. Addition of orthoxynaphtholic acid to a solution of uranvl acetate results in a red coloration, which becomes accentuated as alkaline carbonate is added. If this addition is arrested when the solution is neutral or faintly alkaline, a complex derived from the acid  $[UO_2(C_{10}H_8O \cdot CO_2)_2]H_2$  is obtained. If, however, the solution is faintly acid and the uranyl salt is in considerable excess, a yellow, crystalline compound of the type  $\begin{bmatrix} \text{UO}_2 & \text{C}_{10}\text{H}_8\text{O} & \text{C}_{02} \end{bmatrix} H_2$  separates Protocatechrouranates of the form  $[UO_3(C_6H_3O_2\ CO_2)]H_2$  are obtainable similarly.—C. Antonian: The behaviour of arsenic acid with regard to the absorbent power of soil. Arsenic acid behaves similarly to phosphoric acid in relation to absorption by soil, although it is absorbed to a less degree. With reference to the possibility of the interchange of the phosphoric and arsenic anions, experiment shows that PO<sub>4</sub>" is replaced by AsO<sub>4</sub>" in solutions of arsenic acid, but not in those of arsenates -G. Quagliariello and P. De Lucia: Stereoisomeric transformations of glucose by the action of insulin and of muscular tissue. authors' experiments fail to furnish confirmation of Lundsgaard and Holboll's results, which indicated (1) the existence in the internal liquids of normal animals of an unstable form of glucose (neoglucose) having a very low rotatory power, and (2) the formation of this compound in vitro by the simultaneous action of insulin and fresh muscular tissue on dglucose.—G. Bergami: Action of low temperatures on the crystalline lens. When subjected to low temperatures, the crystalline lens of the sheep or ox behaves like dialysed blood-serum, undergoing partial, reversible coagulation and becoming opaque in the central part Ringer's hypertonic solution produces similar opacity, which disappears if the lens is immersed in Ringer's hypotonic solution; the action of the former solution probably consists in dehydration of the lenticular colloids. The simultaneous action of low temperature and of Ringer's hypertonic solution also results in opacity, reversible at room temperature, even in the crystalline lens of the dog, which is rendered opaque neither by cold nor by the hypertonic solution alone.-G. Cotronei Affinities in Petromyzon according to morphological-systematic and ecological characters.—L. Patanè The perintestinal

layer of the meso-intestine of Balanus The peculiar layer of cells, discovered by Monterosso in the meso-intestine of Balanus perforatus (Bruguière) and termed, first, the peritoneal layer, and later the perintestinal layer, occurs also in Balanus porcatus, B trigonus, and B. cburneus These cells always, or almost always, contain parasomes, and exhibit different morphological and structural peculiarities in the different species—Pia Nalli and G Andreoli: Green's formula in the complex field and the extension of Cauchy's theorem to functions of two complex variables

#### SYDNEY.

Linnean Society of New South Wales, Oct 26.—G H. Hardy: Notes on Australian and exotic Sarcophagid flies A detailed study of the male genitalia would enable the large genus Sarcophaga to be divided into groups of naturally allied species. This is done for some Australian and exotic forms, three groups being defined on this principle, namely, the antilopegroup with six species, the misera-group with seventeen, and the peregrina-group with four Two species from Java are described as new.—Miss H. Claire Weekes Placentation and other phenomena in the scincil lizard, Lygosoma (Hinulia) quoyi. An allantoplacenta is described of a type hitherto not recorded for reptiles. The uterine and allantoic capillaries are exposed at the surface of the maternal and feetal tissues respectively, and scattered cells of the chorionic ectoderm are superficially attached to the maternal wall. This type of placentation is fundamentally similar to that of the marsupial, Perameles.

Royal Society of New South Wales, Nov. 2 -A. R. Penfold The essential oils of two species of Bæckea. B. brevifolia is a small leaved plant of about 18 inches in height which yields more than 11 per cent of essential oil consisting of a- and 3-pinene, cineol, and eudesmol. B limifolia is a tall shrub with drooping branches and white flowers, which yields 0.67per cent of essential oil containing  $\alpha$ - and  $\beta$ -pinene, cymene, cineol (18 per cent.), sesquiterpenes, esters, etc. —M. B. Weich: The moisture content of some eucalyptus woods. Moisture determinations were made on four species of Eucalyptus growing near Sydney, namely, E. eugenvoides, E piperita, E. micrantha. and E. Sieberiana, at intervals over a period of some years. The variation in moisture content which occurs in individual trees, between heartwood and sapwood, and in the same species at different periods, appears to be due to physiological and ecological factors affecting the particular tree in question and cannot be correlated with season or rainfall.—G. S. Currey: The cause of blueing in roses The effect is due to lack of tannin in the cell-sap. Some varieties show a greater tendency to blue than others; "Hadley "represents a blueing type, while "Lady Maureen Stewart "very seldom shows this defect Both types contain the same anthocyanin pigment, namely, cyanın, which occurs in the petals as a glucoside; but the latter contains the larger quantity and there appears to be a direct relationship between the quantity of pigment and tannin present.

#### VIENNA.

#### Life and Death.

THE ages of the Jewish patriarchs as recorded in the Old Testament have provoked much discussion and speculation. Has the span of life decreased during the passage of the centuries? Census statistics show, at any rate in Great Britain, that the expectation of life at birth has increased considerably in recent years. This, however, does not necessarily mean increased longevity, and investigations on remains of men of periods about two thousand years ago suggest that the expectation of life in advanced ages has actually decreased. The men who survived in those days were necessarily of strong constitutions

To those who may have hoped that science will soon provide the means whereby the span of human life may be prolonged, the critical consideration of the factors concerned in the onset of old age given by Sir Humphry Rolleston in the following pages will show that such hope is as yet vain. This does not necessarily imply, however, that the declining years of life cannot, in certain cases, be rendered less irksome.

As is well known, certain primitive organisms, such as Paramocium, may be described as im-Why then are multicellular animals mortal? The mutual influence of the cells of the body upon one another appears to be the basis both for the rise of the multicellular animals in the scale of life and also for their mortality In artificial cultures certain of the cells of the higher organisms can live and multiply indefinitely, provided that they are supplied with suitable nutriment and their waste products removed. But if the latter accumulate to any extent they exert an inhibitory action on the life and reproductive power of the cells: it appears possible, then, that some similar process may account for the gradual decay of the body's cells in old age

On the other hand, one of the most important, if not the dominant factor, in determining the span of life, is inheritance, and this is acted on by the other factors, the sum of which forms the environment in its broadest sense. A favour-

able environment is produced by healthy living, especially the avoidance of excesses of every kind. and in such a case a very fair degree of mental and physical vigour may be retained even to the last. But few people escape lesions, produced by some kind of infection during the course of their life and tending to shorten it. Are there any means by which the span of life may be prolonged or old age rendered less irksome, by which, in fact, the body may be 'rejuvenated'?

On the hypothesis that old age is largely caused by the decay of those cells in the sexual glands which are responsible for the onset of puberty and the development of the secondary sex characters of the individual, Steinach and Voronoff have devised operations to increase the activity of these cells and thus postpone the onset of old age. They have claimed that, by stimulating the individual's own cells to increased activity or by supplying the necessary secretions from foreign cells introduced into the body by grafting, they have been enabled to prolong life and postpone senility in both animals and men. In so far as the symptoms of old age are due to the decrease in the secretions of these glands, it should be possible to relieve them by increasing the supply of these secretions, but to assume that the decrease in the latter plays the sole, or even the major part in the onset of old age, appears to be to take too narrow a view, considering the mutual influence which the cells of the body are known to exert upon one another.

There appears, then, to be no short cut to the abolition of old age and the prolongation of life. Each of us must watch his (or her) step from the day we are born. As Sir Humphry Rolleston expresses it: for a long life there are necessary "a judicious choice of parents, avoidance of disease and worry, moderation in all things, mental and physical exercise, an open-air life, serenity and charity to all men." The prescription seems simple, but the present and coming generations may find it increasingly difficult to carry out under the stress of life under modern conditions.

#### Concerning Old Age.1

By Sir Humphry Rolleston, Bart, KCB

N the simplest forms of animal life—the protozoa—which consist of a single cell, and so stand in the same relation to man that a brick does to a city, multiplication occurs by fission or division into two halves, and as there are now two cells instead of one and no vestige of a corpse, the organism is, as Weismann first insisted, immortal This process may go on indefinitely, and has been watched by Woodruff in Parameeium during 13½ vears, for 8500 generations, comparable to a quarter of a million years of human life, without the occurrence of conjugation—namely, the union of two previously separate organisms, as occurs in the reproduction of higher animals—though periodically rejuvenation appears to take place by means of an independent internal re-organisation (endomixis) of a single cell As the protozoa are, accidents apart, immortal, why is it that animals much higher in the scale never are? It has been shown by culture experiments that the individual cells of man's body are also potentially immortal, but that the necessary conditions for this cannot be realised when they form part of a highly differentiated and specialised complex whole higher walks of the animal kingdom, rejuvenation of the constituent cells is thus rendered much more difficult or impossible, and the process of senescence must be regarded as the penalty for the high degree of individuation entailed in the complicated mechanism of the higher animals and man. But it is interesting to recall that in the humble planarian flat worms the life cycle may be dramatically changed: by starvation they not only become smaller, but also their structure becomes simpler, and their life cycle is reversed by the process of dedifferentiation, reduction, or involution. By alternate starving and feeding, these flat worms have been kept stationary, while others passed through nineteen generations (C. M. Child), thus showing that the duration of existence of cells is not so much a matter of time as of the work or metabolic changes that go on inside them, although it may well be said that such a prolonged existence is not ' life ' according to some views.

Although it is a far cry from amœbæ and flat worms to man, these biological results may have some remote bearing on the conditions influencing the duration of man's life. Not only diet—overand under-feeding, the effects of gross feeding being obviously harmful—but also the more mysterious

influence of the internal secretions provided by the ductless or endocrine glands, the thyroid, pituitary, and the gonads, the activities of which may well be modified by diet, must be taken into account. Disturbance of the endocrine balance, or the equilibrium normally maintained between the hormones or chemical messengers of these endocrine glands, has well-recognised effects on growth and metabolism, and so may influence the rate at which the body lives and wears or rusts out. The significance of the much-discussed 'rejuvenation' produced by Steinach's and Voronoff's operations on the sexual organs proves at any rate that there is much to learn, especially whether or not the duration of life is really prolonged thereby.

#### BIBLICAL AGES

The length of days ascribed to Methuselah (969), to Adam (930, or if the "concert urged by learned men," as Sir Thomas Browne says, that he was 50 or 60 years old when called into being be accepted, making him 980 years at death), to Jared (962), to Seth (912), and others, has of course always excited curiosity. In "Arbor Vitae, or a Physical Account of the Tree of Life in the Garden of Eden," "translated out of the Latine of E M Arrais, M.D., Physician to John the IV King of Portugal, by Richard Browne in" 1683, there is a discussion as to the influence of the emanations of the Tree of Life, the eating of which and the resulting immortality were prevented by cherubims and a flaming sword turning every way, in endowing our first parents and their descendants with longevity, and the conclusion is reached that their length of life was due to the virtues diffused in the air, not only of Eden but also of the neighbouring countries, given off by fruit trees other than the Tree of Life in the Garden of Eden. The longevity of the patriarchs has called forth critical attempts at explanations on the basis of a difference in chronology. But though interesting and perhaps ingenious they are not very convincing, the suggestion that the reputed 'years' were lunar, not solar, containing thirty and not three hundred and sixty-five days, is too radical, for some of the patriarchs would on this interpretation have begotten children before they were ten years of age. The view that the year consisted of three instead of twelve months up to the time of Abraham, when it was extended up to eight months until the time of Joseph, when it first became our full complement of twelve

<sup>&</sup>lt;sup>1</sup> Discourse delivered at the Royal Institution on Friday, May 13.

months, would make Methuselah's age 243 years, which is still excessive by modern standards. The probable explanation is that the patriarchal ages, like those of the mythical golden age of pre-history, existed solely in the minds of later scribes only too anxious to magnify the fathers of mankind. Antediluvian chronology may perhaps be compared with that of the Purānas, or the common scriptures of the ruling Aryan peoples of northern and western India, which contain fragments of truth and much that is imaginary, including in the last category the chronology (Rapson <sup>2</sup>)

The natural or physiological life of man has been thought to be a multiple of the period of growth. Hufeland, taking twenty-five years as the end of adolescence, and accepting Francis Bacon's view that animals live eight times as long as they take to come to maturity, optimistically arrived at two hundred years as the span of man's days on earth, Buffon multiplied fourteen, the age of puberty, by seven, and so concluded that a hundred years was the appointed time. Flourens, on rather different grounds, came to the same estimate, as did the often-quoted centenarian Luigi Cornaro, of Venice (1467–1566), and in more modern times Metchnikoff and Luciani. The number of reputed centenarians, especially in Russia (1 in 1000), Bulgaria (1 in 2000), California (1 in 10,000), and in Ireland (1 in 14,300), is at first sight imposing, but has been sternly discounted and cut down by George Cornewall Lewis, W J. Thoms, and especially by T. E. Young's accurate investigations, and shown, contrary to the general view and other statistics, to be extremely small. Thus we must regard as fabulous the famous examples of Henry Jenkins, Thomas Parr, Katherine, Countess of Desmond, and probably other records, such as the Indian, quoted by Arrais on the authority of many Portuguese Indian governors, who lived more that 335 years, and the truthful tombstone in Carmarthen recording the death in 1831 of Ann David, aged 181 years.

Since the middle of the last century the great reforms in hygiene and sanitation in Great Britain prevented illness and premature death to such an extent that the expectation of life at birth has increased from 39 91 years in 1854 to 51·5 years in 1912 for males, and from 41·9 to 55·35 years for females. These official figures have been kindly given me by Dr T H. C. Stevenson, of the General Register Office, who tells me that provisional rough tables based on the 1921 census and recently published, but not official, show a further increased

expectation of life. This increased expectation of life at birth is due to the prevention of death in early life, and is therefore very different from an increase in longevity. In fact, the statistical conclusion from investigations of the ages recorded on mummies in Egypt two thousand years ago by Karl Pearson, and others quoted by Raymond Pearl, is that the expectation of life at advanced periods has declined. Karl Pearson in 1902 found that, though a man of twenty-five lives on an average fifteen years more than one two thousand years ago, the expectation of life after the age of sixtyeight for a Romano-Egyptian two thousand years ago was greater than for an English man or woman of the same age, and pointed out that with these ancient people at about the beginning of the Christian era it was a case of the survival of the fittest, whereas the difference in the expectation of life at earlier ages is evidence of the great social and sanitary progress that has conquered environment:

While the Psalmist's estimate that "The days of our age are threescore years and ten; though men be so strong that they come to four score years, yet is their strength then but labour and sorrow," is still the common experience, there are of course exceptions that we can all point In his prize essay on comparative longevity written in 1870, Sir Ray Lankester compared persons of abnormal longevity with giants in height which might range up to nine feet; but it is now known that these giants are morbid and examples of acromegaly, described by Pierre Marie in 1886, and it would be curious seriously to regard extreme longevity as a disease, as it is so obviously favoured by absence of that state. On balance, it may be still thought that the physiological age of man is a hundred years, though few there be that reach it. Women live longer than men; and among reputed centenarians also the ratio is much in favour of that popularly said to be the weaker sex; out of 691 reputed centenarian deaths during the ten years 1910-19 inclusive, 504, or 73 per cent., were females, and 187, or 27 per cent., males. 1923 the numbers were 74 females and 22 males.

The reason for the limitation of life, in other words death, has naturally been much debated. Weismann suggested the thesis—a perverse extension of the theory of natural selection and survival of the fittest—that death was an adaptation advantageous to the race Death, which has thus been evolved in the process of advance from a protozoan to the higher metazoan standard of existence, might be regarded as a provision against over-population and famine from insufficiency of

 $<sup>^2</sup>$  Rapson, E. J., in the "Cambridge History of India," 1922, vol. 1, p.  $305\,$ 

the food supplies of the world, and so the natural counterpart to modern artificial birth control Miles Symner, professor of mathematics in Trunty College, Dublin, in the seventeenth century, calculated that in the 1400 years between the Creation and the Flood there would not have been standing room on the earth's surface if the patriarchs, with an average breeding period of four hundred years, begat a son every three years With the present rapid increase of the world's population, thanks to improved sanitation, there have not been wanting estimations that, should no change occur, a few centuries will show the food supply of the world inadequate for its inhabitants (Raymond Pearl, Ravenel)<sup>3</sup>

Metchnikoff considered death to be the result of intoxication from bacterial activity in the alimentary canal, and it has by many been ascribed to arterial disease; the latter is no doubt a common cause of death, but not of the physiological termination of life. But a more satisfactory conception is an inherent constitution determined by heredity, the constituent cells being thus endowed with a certain store of vitality for themselves and their descendants, and that as this runs out the process of involution begins. Cell culture observations, however, suggest that there gradually develops in the cells a substance which inhibits their vitality. Carrel and Ebeling 4 found in cultures of fibroblasts the rate of multiplication and life in vitro varied in inverse ratio to the age of the fowl from which the blood plasma, used in the culture, was taken. It was also found that, with frequent washings to remove waste products, tissue cells can be cultivated indefinitely for years in vitro and have an unlimited capacity for multiplication (Carrel, Champy, and Grandcourt). It would thus appear that there is in old organisms a substance produced in the ageing cells which, entering the blood, exerts an inhibitory action on the life and reproductive power of the tissue cells. On the other hand, Raymond Pearl avoids the assumption of an inhibitory senescent substance in the blood plasma by the simple suggestion that the blood plasma of old animals is itself senescent, and so not such a good culture medium as the blood plasma of the young.

#### \* FACTORS INFLUENCING LONGEVITY.

Experience and that pure and reformed summary of it known as statistics show, as Karl Pearson and A. Graham Bell's figures prove, that inheritance is one of the strongest factors, if not the dominant one, in determining the span of life. The other factors are extrinsic and may be included under the heading of environment in its broadest sense, if we may now use a word which in 1835 John Sterling, in reproaching Carlyle for so doing, described as "barbarous" and "without authority"

Numerous examples of families with long- or with short-lived tendencies will occur to every one, but what heredity can do is perhaps more convincingly established by Raymond Pearl's striking table, from Bell's analysis of the Hyde family, showing the influence of parental ages on that of the offspring: among 184 persons whose parents both hved more than 80 years the average age at death was 52.7 years, whereas among 128 persons whose parents died before 60 years of age their average life was 32.8 years, or nearly 20 years less Forsyth's investigation, carried out on strict actuarial principles, shows that if the reasonably preventable diseases be eliminated, the expectation of life, though increased, would not be so much prolonged as by the influence of a long-lived heritage. We should, therefore, both in our own and their interests, counsel our children to choose their parents carefully As Benjamin Ward Richardson pointed out, the combined ages of one's parents and grandparents divided by six may be of assistance in numbering our days.

A sound stock may overcome the evil influence of environment, such as alcoholism and unhealthy surroundings in towns, and thus explain the occasional longevity of those whose lives have been far from blameless, and the contrast between two aged brothers, one sober, the other intemperate. But even with a poor inheritance care may extend the term of a useful and happy life. Sir Hermann Weber, by practising the precepts of his book on "The Prolongation of Life," led an active and happy existence until within a short time of his death at ninety-five, although his parents died at or before sixty years of age of heart failure and cerebral hæmorrhage—conditions due to high blood pressure and arterio-sclerosis

Of the hereditary factors, inherent vitality of the nervous and the vascular systems are the most important; the force of the nervous tissues calls the tune both in the mental disposition and the physical reactions of the body. As the late Sir William Osler remarked, much depends "on the quality of arterial tissue (vital rubber) which the individual has inherited." This statement, it may incidentally be mentioned, provides the answer to the question,

<sup>&</sup>lt;sup>3</sup> Ravenel, M. P., The Gordon Bell Memorial Lecture, 1925, on "The Prolongation of Life To what Goal is it Tending?" Am. Jour. Public Health, New York, xvi. supplement to February number Carrel and Ebeling, Jour. Exper. Med., Baltimore, 34, 599, 1921.

"What internal evidence is there that Osler has had an unhappy experience with cheap bicycles?" set in an examination paper, analogous to Calverley's famous examination paper on "The Posthumous Papers of the Pickwick Club," on his textbook of medicine. Cazalis' aphorism, "Man is as old as his arteries," is true in so far as the state of the vessels is in certain respects a good index of his prospects, for their condition may be largely determined by heredity, or deteriorated by disease or undue strain, and so provides a record of his family history and personal adventures, but the converse, "the arteries are as old as the man," would not hold good, for arteriosclerosis is not necessarily well marked in very old people

Bodily Conformation.—The long-lived are usually spare and very seldom fat, neither very tall nor very short, very heavy, nor very light Insurance companies are naturally much interested in the bearing of the body-build on longevity, and in America much statistical investigation has been started into problems such as the bearing in persons above the average weight, of the length of the spine, and a comparison of the chest and abdominal girths. From the insurance companies' statistics Dublin <sup>5</sup> found the following rather surprising and confusing results:—Among those over the average weight the prospect of life was better among short and medium height men with short relative spinelengths and with chest girths below the average, and among overweight tall men the outlook was best in those with long relative spine-lengths and chest girths below the average. So that in both of these groups of men above the average weight the presence of a chest measurement below the average was an asset.

Taking environment in its widest sense, the influence of disease in damaging the tissue cells and in accelerating degeneration and atrophic processes resembling those which normally occur must be given due weight. It has been said that only those who have kept their bodies free from disease up to the age of 60 can expect to attain extreme old age (Saundby); but nearly half of the 824 persons between the ages of 80 and 100, analysed by Sir George Humphry, had passed through a severe illness, many of them acute infections It seems highly probable, however, that the influence of an acute illness, the resulting changes being often transient and recoverable, would be much less harmful than that of a long-continued infection or intoxication in producing permanent changes.

There are exceptions, and a terribly notable one is encephalitis epidemica, the 'sleepy sickness' of the lay press. Chronic infections, especially those in connexion with the teeth, are prone to cause rheumatoid arthritis, and the resulting limitation of activity does harm both to the general health and also mentally by impressing the idea of future crippling and incapacity. Acute illness may undoubtedly be the apparent starting-point of old age, more particularly if insufficient time, holiday, and change of scene be not allowed for recovery, the time allotted increasing roughly with the nature of the illness and the patient's age The influence of infections, such as malaria, which Dr. W H S. Jones has shown was an important factor in the decadence of Magna Graecia, and of syphilis, both on the collective and individual health and longevity, need not be laboured

The ideal of medicine is the prevention rather than the cure of disease, and for this end the detection of the earliest stages, and better, of the disposing causes of diseases, is essential. Timely warning about diet, exercise, and manner of life may do much to prevent disease from getting a firm seat on a man's back, and it is not without significance that life assurance companies in America have found it pay to provide periodic medical overhauls to their clients.

Functional activity, mental and physical, plays a great part in keeping the body, when free from disease, trim and slim and in postponing the advent of morbid old age. Occupation with a keen desire to carry it through is so beneficial that some, such as Karl Marx, would regard old age as largely a ques-Speaking of the circle in which tion of will power Madame du Deffand moved, Lytton Strachey<sup>6</sup> says. "They refused to grow old, they almost refused to die Time himself seems to have joined their circle, to have been infected with their politeness, and to have absolved them, to the furthest possible point, from the operation of his laws. Voltaire, d'Argental, Moncrif, Henault, Madame d'Egmont, Madame du Deffand herself, all lived to be well over eighty, with the full zest of their activities unimpaired."

Retirement is a problem beset with anxiety and danger, a successful business man when relieved of routine and able to indulge in idle luxury and without hobbies may rapidly degenerate. He now has to find occupation to kill time instead of time to do all he must; he begins to feel that 'his day is done,' that he has little but his dinner to look forward to, and that at last he is old and a 'has been.'

<sup>&</sup>lt;sup>5</sup> Dublin, L. I., De Lamar Lectures, 1925-1926, p 113

<sup>6 &</sup>quot; Books and Characters," p 83, London, 1922

Thus auto-suggestion, even if not helped by suggestion from outside, hurries him on the downward path, any trifling ailment, such as rheumatism or indigestion due to overfeeding, may arouse very hypochondriacal anticipations, and observation of contemporaries with premature senile changes may feed the flame of this destruc-There is, therefore, a basis tive auto-suggestion for the idea that senility is catching, and for seeking the companionship of the young and thereby letting auto-suggestion work in a constructive direction A well-occupied mind, a happy disposition that thinketh no evil, naturally smiles instead of frowning on a stranger or a new idea, free from anger, hatred, and jealousy, the vice that gives no pleasure to any one, and an attitude of charity in its original and best sense to all, tend to prolong life and make it a happy, healthy prelude to crossing the bar Sir James Crichton-Browne's words, "the best antidote against senile decay is an active interest in human affairs, and those keep young longest who love most."

As showing the influence of long-continued active work, reference may be made to the longevity of dignitaries of the church and the bench, and Prime Ministers, though these are no doubt supermen Among painters there are some examples of very long lives fully occupied up to almost the end— Giovanni Bellini, Michelangelo, Sidney Cooper, Luke Fildes; Titian, for example, was painting with "incomparable steadiness of hand" when cut off by the plague at ninety-nine. Public duties may provide a means of useful and health-maintaining activity; thus during recent years there have been two octogenarian Lord Mayors of London, Sir Thomas Crosby (1911) and Sir John James Baddeley (1921). Compulsory retirement on attaining an age limit in the civil and military services, and now at the older universities, may not always be in the best interests of the individual or of the community; but as the majority of septuagenarians suffer in greater or less degree from pathological old age, it is a good general rule; and those who fall under the axe may comfort themselves on escaping the danger of epitaphs, which add another terror to death, like that bestowed in the "Reminiscences of the University, Town, and County of Cambridge," begun by Henry Gunning when he was over eighty, to the effect that "Professor Edward Christian died in 1823 in the full vigour of his incapacity."

Food.—Experience, ancient and modern, both lay, such as is set forth in Cornaro's "Discourses on a Sober and Temperate Life" (1558), and

medical, as contained in the works of the great George Chevne (who at one time weighed 32 stone before he became a vegetarian), author of "An Essay of Health and Long Life" (1724), Metchnikoff, Henry Thompson the surgeon, and Hermann Weber the physician, agree on the importance of moderation in food. Most centenarians have been small eaters, especially of meat, and there is this advantage in poverty and living on Abernethy's earned sixpence a day, or its present-day equiva-Excess of food, though more gradual in its evil influence, is more generally destructive than alcoholism, and there is much wisdom in Montaigne's dictum, "Man does not die, he kills himself," and in the more dramatic proverb, "You dig your grave with your teeth" As already mentioned, in some lowly forms of life, such as planarian worms, partial starvation prolongs life, and there have not been wanting 'cures' on such economical lines. A simple diet throughout life, and, after growth is completed, obedience to the rule of ceasing to eat before a feeling of repletion cries, 'Hold, enough,' can be confidently recommended.

The influence of alcoholic drinks has been much discussed, and here, as in most problems, the influence of personal predilections may unconsciously tinge our conclusions. But there seems no doubt from collective investigations, such as Sir George Humphry inspired, and insurance companies provide, that hard drinkers are exceptional among the long-lived, and that among the characteristics of those who attain great length of days temperance finds a place. But in spite of the opinion of some enthusiasts that the choice of total abstinence is the only sure path to longevity, the recent investigation, undertaken with all a modern statistician's precautions against fallacies, by Prof. Raymond Pearl 7 on more than 5000 individuals at Baltimore, gives the perhaps not unwelcome verdict that "a moderate use of alcohol does not tend to shorten life." Such an opinion, based on sound data, is of unquestionable value, and this I gladly admit, for my impression was that longcontinued and constant absorption of alcoholic drinks, though always moderate and never amounting to intoxication, did tend to age the conscientious devotee, but a few positive instances are apt to make an undue impression. What constitutes a 'moderate use' is open to the criticism brought by Sir Hermann Weber,8 that what may be so for

 $<sup>^7</sup>$  Pearl, R , "Alcohol and Longevity," 1926 , and leading article,  $Brtt.\ Med\ Jour.,\ 1927,\ 1\ 528$  Weber, Hermann, "On Means for the Prolongation of Life," p. 119, 1908.

one is excess for another, and the proverb, "Wine is the milk of old people," has been countered, as is the habit of proverb quoters, with "Vinum lac veneris," and the danger of exposure to other risks. In forming a conclusion in any given case about the question, to drink or not to drink, the personal equation of the individual must weigh heavily. No doubt total abstinence may suit some better and some worse, and while it certainly eliminates the problem of what is moderate, it equally deprives the aged of the help and comfort that some undoubtedly thus receive

Smoking is on rather a different footing from excessive eating and drinking, as Calverley said, "Stories, I know, are told not to thy credit," but whatever may be true of the effects of the injection of nicotine into cats and rabbits, tobacco smoking has not been proved to cause arterio-sclerosis in As Sir Clifford Allbutt, a non-smoker and with a peculiar susceptibility to tobacco smoke, pointed out, if in any way it does cause arterial disease, the process is so slow, at any rate in most people, that its effects become so mingled with other manifestations of old age as to be almost impossible to discriminate, further, as Ruffer<sup>9</sup> proved by examination of mummies, the ancient Egyptians (1580 BC.-AD 525) certainly had arterio-sclerosis without the consolations of tobacco. There is no doubt that the tolerance to tobacco painfully acquired in youth commonly diminishes with advancing years, and that unpleasant symptoms ranging from irregularity of the heart, abdominal pain to tobacco angina may be the means of transforming a previously inveterate smoker into a total abstainer. Sir George Humphry,10 also a non-smoker, specially investigated the habits in this respect of centenarians, among 19 men, 8 smoked much, 1 a little, 10 not at all, of 30 female centenarians, 4 smoked much, 2 moderately, and 24 not at all It is possible that, as in many people it diminishes appetite. smoking may exert a beneficial influence by preventing over-eating.

There are statistics to show that people in the country live longer than those in towns.

The advice then to give others, and even to practise ourselves, should include a judicious choice of parents, avoidance of disease and worry, moderation in all things, mental and physical exercise, an open-air life, serenity and charity to all men. Leonard Williams's epigrammatic summary is

easier to remember "Fresh air, meagre food, freedom from care"

The onset of what is popularly called old age varies in different countries. for example, the wheels of life run much faster in tropical countries, such as India, than in temperate latitudes In the same race there is considerable variation. one man at sixty is prematurely senile—the subject of pathological old age—whereas another aged eighty is vigorous in body and alert in mind. In women the menopause is a milestone, and at any rate is the frontier of the territory of old age. There has been said to be a similar chimacteric in man at fifty or sixty, due to changes in the reproductive organs, but without, I believe, any solid foundation. it may be a survival of the ancient conception of the grand climacterics at 49 (a multiple of the number 7), at 63 (7 multiplied by the magical number 9 of the Arabians), and at 81 Sir Henry Holland in 1873 described the "climacteric disease," which admittedly seldom came on without some previous event, such as cold, gout, a bout of drinking, recent marriage, or bereavement There can be no possible shadow of doubt that after an illness recovery becomes slower as the years roll by, and that often, especially when the proper period of convalescent repose is abbreviated, the onset of old age is first noticed after an illness; the moral is to hurry slowly after illness, be it influenza, operation, or worse.

A senile climacteric about the latter part of the seventh or eighth decade in man, marking the dividing line between old age and decrepitude, as drawn in Chapt. xii. of Ecclesiastes, has been described by Nascher, but it cannot be regarded as comparable to the menopause in the other sex To put the beginning of old age at fifty or even sixty in man would no doubt raise the protest that it is only the elastic period of middle age. In truth there is so much variation that a rigid date cannot be fixed. In healthy people the advent of old age is so gradual that the individual himself has no suspicion of it, and very likely secretly preens himself on looking ten years younger than his years and his contemporaries, whose changed appearance arouses self-congratulation rather than self-examination. Perhaps the suspicion suddenly breaks upon him by overhearing a chance remark of others, by seeing an unwonted reflection of his figure in a mirror, or by some nice girl offering him her seat in an omnibus. Or a holiday may break to him that he cannot walk as of yore because of undue fatigue, or he is held up by shortness of breath or pain on unwonted exertion.

#### THE PHYSIOLOGY OF OLD AGE

While the whole body does not age at the same rate, there is a general and progressive dimmution in functional activity corresponding to the atrophic involution of the cells of the organs and The response to stimuli of all sorts is diminished, and this sluggish reaction contrasts with the ready and comparatively exaggerated response to both normal and pathological stimuli in early life. The popular opinion that age is second childhood may be correct in that there is some resemblance between undeveloped and failing mental and physical powers, but there is an enormous difference between the ever actively moving child and the impassiveness of real old age. This failure of the power of reacting to stimuli is seen in the sense organs, few people over sixty have perfect hearing, although most of us do not know it; and, apart from loss of acuity, they often do not take in general conversation so well as others unless their attention is braced up for the purpose The emotions are less active, the death of friends is less of a grief, and so the individual tends to become isolated and to live more on past than on present-day impressions; hence a well-educated man may become more composed and satisfied, whereas one without intellectual interests may sink into mental torpor, vanity, and egocentricity, with the development of fads about health, undue garrulity, and a confirmed attitude of the laudator temporis acti. In what may be regarded as normal old age psychical activity wanes; new ideas do not bubble up, and when brought to the notice are not impetuously accepted. On the other hand, there is more of the philosophic calm born of what, when twitted with impatience, the young university don dismissed as "that greatly overrated property experience." Forgetfulness first of names, and much later of recent events, and mental fatigue are other evidences of the change. With loss of memory comes the habit of repeating the same story or remark, of mislaying things, and of becoming careless about the external graces.

Statements that the race is all to "the younger generation," and that forty marks the end of useful work in the world, are of course exaggerations, and many examples could be brought forward of masterpieces in art, literature, and science which have come from men much above that age. But taking the average, it must be admitted that the elasticity, imaginative power, and originality of mind that produce works of genius and great advances are seldom found in those who have two

score years and ten to their credit. In the early stage, when a suspicion of the approach of age begins to dawn, there may be defensive action in the apeing of the young, so as to conceal the true age: a man may withdraw the date of his birth from "Who's Who" and other books of reference, and a mother has been known to delay the coming-out of her daughter

While calmer and of more mature judgment as . a rule, many, but perhaps not quite normal, old people become more anxious and apprehensive. like their gait, their will power is hesitant animals the instinct of self-preservation seems to fade, and as their time draws nigh have perhaps, if we could only know, a desire for death, comparable to that for "his brother Sleep", old people, though they often complain of their state, generally have what Matthew Arnold called passionate, absorbing, almost blood-thirsty clinging to life" This, however, is not universal, and shortly before the end often disappears so that death is regarded as a welcome release, as is borne out by the famous William Hunter's last words when only sixty-five, "If I had strength enough to hold a pen, I would write how easy and pleasant a thing it is to die."

Muscular power and ability to walk as far and as fast as of yore diminish; the muscles and the glands of the intestine become sluggish so that constipation results; the diminished secretion of cutaneous perspiration makes the skin dry, and the bodily exchanges, as shown by basal metabolism estimations, are less (Aub and Dubois 11; Legrand 12) But except that the temperature in the axilla is lower than normal on account of the diminished blood supply to the skin, the internal temperature of the body is not, as might be expected, and indeed has been stated, lowered. The explanation appears to be that, although there is less heat produced in the body, there is less loss of heat from the dry skin on account of its poor vascular supply. Diminished sensibility to pain, both mental and bodily, is a beneficial relief, and suggests that with the gradual involution and approach to physiological death this warning will no longer be needed This in some degree accounts for the latency of disease, such as pneumonia, urinary calculi, gallstones, or cancer, sometimes shown by the aged. There are, however, exceptions, such as pain after zona (shingles) and obstinate itching. Sleep is less continuous than in youth, and early waking is common. Recovery from illness

Aub and Dubois, Arch. Int. Med., Chicago, 19, 823, 1917
 Legrand, R., Rev. franç. de l'encrinolog., Paris, 4, 199, 1926.

is slower, wounds and fractures of bones take longer to heal, and intracapsular fracture of the neck of the femur, which is prone to occur from the thinning of the bone and the altered angle at the junction of the shaft and the neck of the bone, is a serious accident, often followed, as if it were the last straw, by dissolution The old react somewhat differently to drugs, responding less promptly, so that some, such as purgatives, may be needed in considerable quantities. On the other hand, tolerance, as to tobacco, may become so much diminished that idiosyncrasies to certain drugs may appear; morphine should be preceded by a previous dose of atropine to protect the senescent respiratory centre from being put to sleep, but the old are scarcely so susceptible as children to this

Though a gradually rising blood pressure is commonly seen to accompany the passing years, a high blood pressure is not a feature of old age; in fact, it might be said that those who attain great length of days do so, in part at least, because they have not had a high blood pressure to wear out and thicken their blood vessels. The pulse often shows intermittence (extrasystoles); this was so in one-fifth of the 824 persons analysed by Sir George Humphry, and though sometimes a cause of annoyance is not of any import.

#### NORMAL STRUCTURAL CHANGES IN OLD AGE.

Just as it may be difficult to state dogmatically that an old person is purely in a state of physiological senescence, as opposed to a condition in which past illnesses and infections have played a part so that there is a combination of physiological and morbid influences—of senescence and senility—so it may be hard to draw a hard-and-fast line between the structural changes of physiological involution and atrophy and those that may be regarded as pathological, especially as disease may accelerate the involutionary changes. It is probable that the ideal of physiological involution is so rare that at best the changes are but relatively physiological. The general atrophy is shown by loss of weight, for how rare it is that a really old person is fat, in fact, obesity is a sign that the normal metabolism, or exchanges in the body, is not physiological. The atrophic process does not proceed equally in all the constituents of the body; the nobler active cells are much more affected than the supporting fibrous tissues. The nerve cells in the brain and spinal cord become small, degenerated, and pigmented, and the brain as a whole weighs less. Arcus senilis, though occasionally seen in early life, is like grey or white hair, an accompaniment of age and due to degeneration, changes in the crystalline lens cause presbyopia, which may be brought on prematurely by toxamia, it is said, of intestinal origin (E. Clarke)

The fall of the hair is not necessarily confined to the aged; a rare, but curious, effect is that after illness naturally brown hair has been reported in place of that previously white. The skin becomes dry, glossy, inelastic like parchment, and wrinkled from atrophy of the fat, muscle, and elastic tissue, especially on the backs of the hands. From diminution of the blood supply there is an ivory pallor somewhat relieved by pigmented areas and dark brown patches of seborrhæic eczema, when in such a condition of impaired resistance the skin readily becomes damaged and is prone to infection, so that pruritus and even indolent ulcers may result. From atrophy of fat the veins become more prominent, and the appearance of small red angiomas on the trunk is common in middle age.

Like the hair, the teeth become few; Sir George Humphry found that above eighty years of age the average number left was six in men and three m women; it may not be so many now. Sir Isaac Newton, however, at the age of eighty-five was said to have lost only one tooth The loss of teeth might perhaps be regarded as a hint that there is no longer need for so much food. With the loss of teeth the lower jaw returns to its shape in the infant, hence the 'nutcracker' aspect of the edentulous face. The bones of the skeleton get thinner, but retain their length and usually their form. The back becomes bowed from muscular weakness, but the cartilages of the ribs and the larvnx do not become calcified except as a pathological event comparable to calcification of the arteries. It is interesting to speculate if there is any relation between the atrophy of bone and the enlargement of the prostate which occurs in a certain number of elderly men; for Grove and Vines found a deficiency of calcium in the blood of patients with enlarged prostates, and obtained benefit by giving extract of parathyroid gland, which controls calcium metabolism

The heart is probably less altered than the other organs and tissues of the body, and indeed its efficiency must be essential for prolonged existence, as may be shown by statistics to the effect that from sixty to ninety years of age death is more often due to failure of the circulatory system, sometimes a blessed painless passing away in sleep, than to any other cause, whereas before sixty, failure of

the respiratory system is most responsible, to keep the heart in a healthy condition exercise is important.

The blood of healthy octogenarians does not necessarily show any change in the number of the red blood corpuscles and the amount of hæmoglobin, though pallor of the skin may suggest an anæmia which does not exist. Sometimes there is secondary anæmia resembling the Addisonian type, this is either due to morbid influences or to a more advanced atrophy and involution of the red bone marrow than usually occurs. The lymphatic glands, the spleen, and the leucoblastic bone marrow all, like the other organs, diminish in size, but this does not appear to influence the leucocyte count.

As already mentioned, arterio-sclerosis is neither the necessary accompaniment nor the cause of healthy old age. But it is very frequent in old people, and often causes premature sensity, renal disease, and difficulty in walking (intermittent claudication or limp)

The endocrine glands share in the general involution, but in spite of attempts to find in them, and especially in the thyroid and the interstitual cells of the gonads, the elixir of life, this desideratum is still to seek

The sexual organs slowly atrophy, with the exception that the prostate gets larger in most men after the age of fifty, though a small percentage only of them suffer from it. The formation of fibro-myomatous tumours of the uterus and of cystic involutionary changes in the mammary glands of women appear to be analogous to that in the prostate

#### HEALTHY AND PATHOLOGICAL OLD AGE.

From the time of Terence, Cicero, and Sanatorius, old age has been regarded as a disease, and Samuel Johnson remarked, "My diseases are an asthma, a dropsy, and, what is less curable, seventyfive." But it is important to remember that there are two kinds of old age: (1) The healthy old age. which I almost called the normal, but perhaps, as this might imply that it is the usual or average form, it is better not so described; and (ii) the commoner, in which the body has not simply grown old, but shows the relics and results of past disease, accumulated in the passage of years. It has been said, and with fair probability, that most people over sixty years of age have some focus of infection, such as those in connexion with the teeth, the accessory nasal sinuses, the prostate, or gall bladder; these sources of poisoning undermine the general health and age the tissues, especially when they are beginning to undergo the natural process of involution and atrophy. To draw a hard-and-fast line between healthy old age (senescence) and old age partially caused by some disease may, in individual instances, be difficult or even impossible, they so often overlap. It is, however, observance of pathological old age that accounts for the pity, if not dislike, with which it is commonly viewed, and for the opinion expressed by many people that they have no wish to live to a great age

The influence of adverse conditions, unhealthy surroundings, infections, and disease in shortening life and producing a pathological, that is, unnatural, old age is seen by comparing the physiological existence of man, which not unreasonably may be put at a hundred years, with the average expectation of life at birth in England and Wales-55 35 years for females and 515 years for males age of fifty to sixty is that when some common diseases, such as arterio-sclerosis, failing heart. kidney disease, cerebral hæmorrhage, liver disease, and cancer, take a heavy toll. Those who survive with cardio-vascular disease are prematurely restricted in their activities and so help to increase the unhappy impression that advancing years has in the popular mind.

There are many definitions of disease, or 'want of ease,' and as good a one as any is a want of adjustment between the individual and his surroundings. The frequency with which those advanced in years suffer pain and discomfort is evidence of more than length of days; for example, rheumatism is the result of some focus of infection. Arterio-sclerosis, the result of past or present high blood pressure or of poisons—bacterial, metabolic, and of intestinal origin—is very common in old people, but is not, at least in an extreme degree, a necessary accompaniment

# THE DESCRIPTION OF OLD AGE IN THE TWELFTH CHAPTER OF ECCLESIASTES.

In connexion with old age, every one must recall the famous description in the first six verses of the twelfth chapter of Ecclesiastes, beginning, "Remember now thy Creator in the days of thy youth, while the evil days come not, nor the years draw nigh, when thou shalt say, I have no pleasure in them." Formerly ascribed to King Solomon (977 B.C.), the Book of Ecclesiastes (in Hebrew Koheleth = the preacher) has been shown by the higher criticism to date only from the end of the third century B.C. In his attractive work, "A

Gentle Cynic," 13 the late Prof. Morris Jastrow, jun, of Philadelphia, argued that the book of Ecclesiastes as it appears in the authorised version, consists of (1) the original, cynical, but good-natured obiter dicta of the unknown dilettante who preferred to veil his identity under the name of Koheleth, and (ii) additions and modifications made by various hands to render it more orthodox and compatible with the tradition that it was written by Solomon Thus the admonition "of making books there is no end; and much study is a weariness of the flesh," may very probably have been intended as a hint that Koheleth's views should not be taken too seriously. Following this conception, Jastrow reconstructed the text of the book of Ecclesiastes to what he argued was its original form, and compared it with the more modern writings of Omar Khavvám and Heinrich Heine. As we all must have speculated over the correct interpretation of the various metaphors in this description of the last stage of life, the explanations offered by others, such as Andreas Laurentius 14 (1599), Master Peter Lowe 15 (1612), founder of the Faculty of Physicians and Surgeons of Glasgow, Bishop J Hall <sup>16</sup> (1633), Richard Mead <sup>17</sup> (1775), and Jastrow may be very briefly mentioned 1666, John Smith devoted a book of 266 pages to elucidate these six verses which contain 207 words -" King Solomon's Portraiture of Old Age wherein is contained A Sacred Anatomy both of Soul and Body" He is peculiar in authorship on this subject at his early age, thirty-five years, for nearly all the other writers on this topic, such as Cornaro, Sir Anthony Carlisle, Charcot, Sir George Humphry, Sir Hermann Weber, and Robert Saundby, not to mention and embarrass those happily with us, have been approaching "the sere, the yellow leaf," and have perhaps been moved to their labours by the maxim, "Physician, cure thyself."

The second verse, "While the sun, or the light, or the moon, or the stars, be not darkened, nor the clouds return after the rain," is regarded by Laurentius, Lowe, and Hall as referring to the ocular disabilities of old age, whereas Smith and Mead consider that mental failure and depression are meant As regards the third verse, "In the

in 1616.

day when the keepers of the house [the hands] shall tremble, and the strong men | the legs | shall bow themselves [become bent], and the grinders [teeth] cease because they are few, and those that look out of the windows [the eyes] be darkened," there is general agreement, Lowe specially designating cataract as meant in the last sentence. "And the doors shall be shut in the streets" is regarded as referring to the mouth by Laurentius and Mead, and to the various orifices, including the resultsconstipation and dysuria—by Smith, "when the sound of grinding is low" is considered by Jastrow to mean impaired hearing, and by Smith as a lowered rate of metabolic processes, such as assimilation, blood formation, and various secretions. "And he shall rise up at the voice of the bird" implies, according to Smith and Mead, the early waking of the elderly, " and all the daughters of musick shall be brought low" signifies to Laurentius the failure of voice, to Mead deafness, and to Smith all the organs concerned with sounds -namely, the lips, tongue, larynx, and the auditory apparatus. "Also when they shall be afraid of that which is high, and fears shall be in the way" is regarded by Smith as describing the general mental attitude of anxiety for things both small and great and a bad head for height, but a more modern commentator suggests that "afraid of that which is high" refers to dyspnæa on climbing a hill. "And the almond tree shall flourish" is by Laurentius, Hall, and Smith thought to refer to the white hair or 'churchyard flowers' of the old, but Mead argued that loss of smell is meant. "And the grasshopper shall be a burden" has been very variously interpreted. Hall is content to accept the literal meaning that the least weight is a nuisance, Laurentius and Lowe understand edema of the legs; John Smith that the aged body undergoes the reverse change of shrivelling, hardening, and angularity. In the sixth verse the words "or ever the silver cord be loosed" refer, according to Laurentius, Lowe, Mead, and Jastrow, to kyphosis, but Smith translates them into paralysis of the spinal cord and nerves. "Or the golden bowl be broken" signifies cardiac failure to Laurentius and Lowe, but cerebral hæmorrhage to Smith, who thus explains the next line, "or the pitcher [the veins] be broken at the fountain [the right ventricle], or the wheel |the arterial circulation] broken at the cistern [the left ventricle]," and therefore concludes that King Solomon was perfectly acquainted with the circulation of the blood discovered by William Harvey

 <sup>13 &</sup>quot;The Gentle Cynic, being a Translation of the Book of Koheleth, commonly known as Ecclesiastes, stripped of later Additions, also its Origin, Growth, and Interpretation," by Moiris Jastrow, junior, 1919, J B Lippincott Co

#### DISEASES OF OLD AGE

The diseases of old age would make a long chapter In each of the ages of man's strange eventful history some diseases are particularly prominent, and others very unusual or never occur. but, generally speaking, the influence of age consists in modifying the character rather than in initiating special forms of disease A convenient method of considering the subject would be under the two heads of diseases (1) occurring in the aged, and (ii) those more or less confined to the last phase Diseases common to all or most stages of life are in old age less acute, less dramatic, and more prone to be latent: in Charcot's words, the organs suffer in silence without any local or general disturbance, though sudden collapse may occur. pneumonia, which Osler called "the friend of the aged," because by a short and rarely painful illness it relieves them from those "cold gradations of decay" that make the last stage of all so distressing, is often so latent that death is ascribed to senile decay.

There is, as already pointed out, a great contrast between early and late life in the reaction to disease, but in acute disease, contrary to what might be expected from what has been said about the sluggish response, there is no tendency to absence of fever in the aged. In life's journey the scars and effects of disease accumulate so that rheumatoid arthritis and crippling arteriosclerosis and its results, and some forms of cancer, become more prominent. Dr. T. H. C. Stevenson, of the General Register Office, has kindly provided me with statistics showing that cancer is not a disease of the period from fifty to seventy, rather than of the more advanced old age; in fact, recent returns, with a few apparent and doubtful exceptions, show that, on the whole, mortality from cancer of the more accessible sites continues to increase up to extreme old age, whereas that from the less easily accessible does not, the decrease in extreme old age being greatest for cancer in parts of the body—the stomach and intestmes—where it is more likely to escape detection <sup>18</sup> In America it has been estimated that 10 per cent. of all old people die from unsuspected cancer (Wood <sup>19</sup>). It has, however, been argued that old age alone does not specially favour the development of cancer, and that the relationship is entirely indirect by providing opportunity for long-continued irritation (Murray <sup>20</sup>). In old age repeated exposure to the infections responsible for fevers, such as measles, scarlet, diphtheria, and typhoid, has produced a considerable degree of protection. Pneumonia and erysipelas, however, are prone to recur.

Many of the affections of the old are the result of arterio-sclerosis, a legacy of the middle period of life, which has continued to progress, and by interfering with the circulation produces serious degeneration in the important cells of the organs. especially in the central nervous system, thus from changes in the brain and spinal cord there result senile dementia and various forms of paralysis. and from implication of the arteries of the lower limbs difficulty in walking from cramp and intermittent claudication, and senile gangrene. There is a form of tremor in the elderly which often affects the head, and paralysis agitans or Parkinson's disease—so called after its describer, James Parkinson, a humble general practitioner in Hoxton. who was also a palæontologist and author of pamphlets advocating bloodless revolution—though not confined to old age, is most usual then; it is of particular interest because its features are closely imitated by the result of encephalitis epidemica, which since the War has been comparatively common in the young, and so is a good example of the degenerative effects of disease imitating those seen in advanced age.

#### British Association Addresses.

A Message from H R H. The Prince of Wales, K G , F R S , on Laying Down the Presidency of the Association.  $^1$ 

Association has come to an end, and I can only express my regret to the members of the Association, and to our hosts the City and University of Leeds, that I am unable to attend personally in order to take my leave.

At Oxford last year I ventured in my address to lay before the meeting a view of the relations between science and the State I felt subsequently some justification for having chosen this topic, when I observed in the proceedings of the Imperial and Colonial Conferences of the past year the extraordinary emphasis laid upon the value of scientific research in relation to imperial development Both conferences set up special committees on research, and we cannot but believe and rejoice that the foundations of an imperial scientific service are being firmly laid. The Prime Minister of Australia indicated "the application of science both to our primary and secondary industries" as "the most important thing for Empire trade"; more recently our ex-president, the Earl of Balfour, invited the attention of the House of Lords to "the enormous value of the work given by men of science, with the most lavish generosity," to the study of problems of the common welfare.

Such events as these place it beyond doubt that one of the main objects of the British Association itself is in process of achievement, namely, that of "obtaining more general attention for the objects of science" The Association, the so-called parliament of science, is one of the chief instruments to that end, and I trust that the public support will continue, in increasing measure, to be accorded to its work. Its powers, I am happy to say, have been very materially strengthened, during my own term of office, through the splendid generosity of Sir Alfred Yarrow, in making a gift of £10,000 for the general purposes of the Association, to be expended, in accordance with his wise provision, in the course of twenty years. I gladly take this opportunity of publicly repeating the thanks of the Association to Sir Alfred Yarrow.

In resigning the chair to Sir Arthur Keith, I can whole-heartedly congratulate the Association on its choice of my successor. His name stands very high in the science of man's origin and early biological history I have reason to believe that when, any one in this country digs up a bone his first instinct (subject to the intervention of the police) is to send it to Sir Arthur Keith You are to hear from him an address on Darwinism as it stands to-day-a subject of perennial interest, and more than once one of warm controversy at our own meetings The occasion of the presidential address does not (I am thankful to say) lend itself to controversy, but the warmth I am sure you will supply in your welcome to Sir Arthur Keith, and, meeting as you are in Leeds, that warmth will be increased by the traditional quality of Yorkshire hospitality.

EDWARD P, President.

<sup>&</sup>lt;sup>1</sup> Read at the maugural meeting of the Association in Leeds on Wednesday evening, Aug. 31.

### Darwin's Theory of Man's Descent as it Stands To-day.1

By Prof Sir Arthur Keith, M.D., D.Sc., LL.D., F.R.S.

Y first duty as your president, and it is a very pleasant one, is to send the following message in your name to HRH The Prince of Wales Your Royal Highness,

The British Association for the Advancement of Science, now assembled in Leeds to begin another session, cannot allow your year of office to terminate without offering to you sincere and humble congratulations on the happy results which have attended your presidency A year ago, in the historic city of Oxford, you did British science the signal honour of coming among us as our president, the meeting you then maugurated set a standard which future gatherings will strive to emulate. The inspiring message you then addressed to us, and through us to men of science in every part of the Empire, has already borne fruit We are within sight of a closer union, for which the Association itself has always striven, between men of science overseas and their colleagues at home, in their endeavour to solve problems of Imperial concern. It is too soon as yet to assess the value of the harvest of science planted under your ægis, for the best vintages of science mature slowly, but of this we are certain: the interest Your Royal Highness has taken in the work of this Association will prove a permanent source of encouragement for all who work for the betterment of life through increase of knowledge. To-night we proudly add your presidential banner to those of the great men of science who have presided over this Association since its inception at York ninety-six years ago.

#### SUBJECT OF ADDRESS.

In olden times men kept their calendars by naming each year according to its outstanding event. I have no doubt that in future times the historian of this Association, when he comes to distinguish the presidential year which opened so auspiciously in Oxford twelve months ago, will be moved to revert to this ancient custom and name it the 'Prince's Year.' And I am under no misapprehension as to what will happen when our historian comes to the term which I have now the honour of inaugurating at Leeds; he will immediately relapse to the normal system of numerical notation. Nor will our historian fail to note, should he be moved to contrast the meeting at Oxford with that which now begins at Leeds, that some mis-

chievous sprite seems to have tampered with the affairs of this Association. For how otherwise could he explain the fortune which fell to ancient Oxford, the home of history? To her lot fell a brilliant discourse on the application of science to the betterment of human lives, while Leeds, a city whose life's blood depends on the successful application of science to industry, had to endure, as best she could, a discourse on the theme of ancient history. For the subject of my address is man's remote history. Fifty-five years have come and gone since Charles Darwin wrote a history of man's descent. How does his work stand the test of time? This is the question I propose to discuss in the brief hour at my disposal.

#### THE OPENING SHOT IN THE DARWINIAN BATTLE

In tracing the course of events which led up to our present conception of man's origin, no place could serve as a historical starting-point so well as Leeds In this city was fired the first verbal shot of that long and bitter strife which ended in the overthrow of those who defended the Biblical account of man's creation and in a victory for Darwin. On September 24, 1858—sixty-nme years ago—the British Association assembled in this city, Sir Richard Owen, the first anatomist of his age, stood where I now stand. He had prepared a long address, four times the length of the one I propose to read, and surveyed, as he was well qualified to do, the whole realm of science; but only those parts which concern man's origin require our attention now. He cited evidence which suggested a much earlier date for the appearance of man on earth than was sanctioned by Biblical records, but poured scorn on the idea that man was merely a transmuted ape. He declared to the assembled Association that the differences betwee man and ape were so great that it was necessary, in his opinion, to assign mankind to an altogether separate order in the animal kingdom statement fell from the president's lips there was at least one man in the audience whose spirit of opposition was roused—Thomas Henry Huxley— Owen's young and rising antagonist

#### OWEN AND HUXLEY.

I have picked out Huxley from the audiencer because it is necessary, for the development of my theme, that we should give him our attention for a moment. We know what Huxley's feelings were

 $<sup>^{\</sup>rm 1}$  Presidential address delivered to the British Association at Leeds on Aug  $\,31$ 

towards Owen at the date of the Leeds meeting. Six months before, he had told his sister that "an interneone feud rages between Owen and myself," and on the eve of his departure for Leeds he wrote to Hooker. "The interesting question arises: shall I have a row with the great O there?" I am glad to say the Leeds meeting passed off amicably, but it settled in Huxley's mind what the 'row' was to be about when it came. It was to concern man's rightful position in the scale of living things

#### Man's Position in the Animal Kingdom.

Two years later, in 1860, when the British Association met in Oxford, Owen gave Huxley the In the course of a discusopportunity he desired sion Owen repeated the statement made at Leeds as to man's separate position, claiming that the human brain had certain structural features never seen in the brain of anthropoid apes. Huxley's reply was a brief and emphatic denial with a promise to produce evidence in due course—which was faithfully kept This opening passage at arms between our protagonists was followed two days later by that spectacular fight—the most memorable in the history of our Association—in which the Bishop of Oxford, the representative of Owen and of orthodoxy, left his scalp in Huxley's hands. To make his victory decisive and abiding, Huxley published, early in 1863, "The Evidences of Man's Place in Nature," a book which has a very direct bearing on the subject of my discourse. It settled for all time that man's rightful position is among the Primates, and that as we anatomists weigh evidence, his nearest living kin are the anthropoid apes.

#### OWEN'S OPINION OF DARWINISM

My aim is to make clear the foundations on which rest our present-day conception of man's origin. The address delivered by my predecessor from this chair at the Leeds meeting of 1858 has given me the opportunity of placing Huxley's fundamental conception of man's nature in a historical setting. I must now turn to another issue which Sir Richard Owen merely touched upon, but which is of supreme interest to us now. He spent the summer in London, just as I have done, writing his address for Leeds and keeping an eye on what was happening at scientific meetings In his case something really interesting happened Sir Charles Lyell and Sir Joseph Hooker left with the Linnean Society what appeared to be an ordinary roll of manuscript, but what in reality was a parcel charged with high explosives, prepared by two very innocentlooking men—Alfred Russel Wallace and Charles Darwin. As a matter of honesty it must be admitted that these two men were well aware of the deadly nature of its contents, and knew that if an explosion occurred, man himself, the crown of creation, could not escape its destructive effects. Owen examined the contents of the parcel and came to the conclusion that they were not dangerous; at least, he manifested no sign of alarm in his presidential address. He dismissed both Wallace and Darwin, particularly Darwin, in the briefest of paragraphs, at the same time citing passages from his own work to prove that the conception of natural selection as an evolutionary force was one which he had already recognised

## THE TRANSFORMATION OF OUR OUTLOOK ON MAN'S ORIGIN.

As I address these words to you I cannot help marvelling over the difference between our outlook to-day and that of the audience which Sir Richard Owen had to face in this city sixty-nine years ago The vast assemblage which confronted him was convinced, almost without a dissentient, that man had appeared on earth by a special act of creation, whereas the audience which I have now the honour of addressing, and that larger congregation which the wonders of wireless bring within the reach of my voice, if not convinced Darwinists are yet prepared to believe, when full proofs are forthcoming, that man began his career as a humble primate animal, and has reached his present estate by the action and reaction of biological forces which have been and are ever at work within his body and brain.

#### DARWIN'S GENERALSHIP.

This transformation of outlook on man's origin is one of the marvels of the nineteenth century, and to see how it was effected we must turn our attention for a little while to the village of Down in the Kentish uplands, and note what Charles Darwin was doing on the very day that Sir Richard Owen was delivering his address here in Leeds. He sat in his study struggling with the first chapter of a new book; but no one foresaw, Owen least of all, that the publication of the completed book, "The Origin of Species," fifteen months later (1859), was to effect a sweeping revolution in our way of looking at living things and to initiate a new period in human thought—the Darwinian period—in which we still are Without knowing it, Darwin was a consummate general. He did not launch his first campaign until he had spent twenty-two years in stocking his arsenal with ample stores of tested and assorted fact. Having won territory with "The Origin of Species," he immediately set to work to consolidate his gains by the publication in 1868 of another book, "The Variation of Animals and Plants under Domestication"—a great and valuable treasury of biological observation. Having thus established an advanced base, he moved forwards on his final objective—the problem of human beginnings—by the publication of "The Descent of Man" (1871), and that citadel capitulated to him To make victory doubly certain he issued in the following year—1872—"The Expression of the Emotions in Man and Animals" Many a soldier of truth had attempted this citadel before Darwin's day, but they failed because they had neither his generalship nor his artillery.

#### HISTORY AS WRITTEN BY DARWIN.

Will Darwin's victory endure for all time? Before attempting to answer this question, let us look at what kind of book "The Descent of Man" is. It is a book of history—the history of man, written in a new way—the way discovered by Charles Darwin. Permit me to illustrate the Darwinian way of writing history If a history of the modern bicycle had to be written in the orthodox way, then we should search dated records until every stage was found which linked the two-wheeled hobbyhorse, bestrode by tall-hatted fashionable men at the beginning of the nuneteenth century, to the modern 'jeopardy' which now flashes past us m country lanes But suppose there were no dated records—only a jumble of antiquated machines stored in the cellar of a museum. We should, in this case, have to adopt Darwin's way of writing history. By an exact and systematic comparison of one machine with another we could infer the relationship of one to another and tell the order of their appearance, but as to the date at which each type appeared and the length of time it remained in fashion, we could say very little. It was by adopting this circumstantial method that Darwin succeeded in writing the history of man gathered historical documents from the body and behaviour of man and compared them with observations made on the body and behaviour of every animal which showed the least resemblance to man. He studied all that was known in his day of man's embryological history, and noted resemblances and differences in the corresponding histories of other animals. He took into consideration the manner in which the living tissues of man react to disease, to drugs, and to environment, he had to account for the existence of diverse races of mankind a logical analysis of his facts Darwin reconstructed and wrote a history of man.

DARWIN'S POSITION HAS BECOME IMPREGNABLE.

Fifty-six years have come and gone since that history was written, an enormous body of new evidence has poured in upon us. We are now able to fill in many pages which Darwin had perforce to leave blank, and we have found it necessary to alter details in his narrative, but the fundamentals of Darwin's outline of man's history remain unshaken Nay, so strong has his position become that I am convinced that it never can be shaken

#### THE EVIDENCE OF FOSSIL REMAINS

Why do I say so confidently that Darwin's position has become impregnable? It is because: of what has happened since his death in 1882. Since then we have succeeded in tracing man by means of his fossil remains and by his stone implements backwards in time to the very beginning of that period of the earth's history to which the name Pleistocene is given We thus reach a point in history which is distant from us at least 200,000 years, perhaps three times that amount. Nay, we have gone farther, and traced him into the older and longer period which preceded the Pleistocene the Phocene It was in strata laid down by a stream in Java during the latter part of the Pliocene period that Dr. Eugene Dubois found, ten years after Darwin's death, the fossil remains of that remarkable representative of primitive humanity to which he gave the name Pithecanthropus, or apeman, from Pliocene deposits of East Anglia Mr. Reid Moir has recovered rude stone implements. If Darwin was right, then as we trace man backwards in the scale of time he should become more bestial in form—nearer to the ape That is what we have found. But if we regard Pithecanthropus with his small and simple yet human brain as a fair representative of the men of the Pliocene period, then evolution must have proceeded at an unexpectedly rapid rate to culminate to-day in the higher races of mankind.

# Man's Descent has not been in a Straight Line.

The evidence of man's evolution from an ape-like being, obtained from a study of fossil remains, is definite and irrefutable, but the process has been infinitely more complex than was suspected in Darwin's time. Our older and discarded conception of man's transformation was depicted in that well-known diagram which showed a single file of skeletons, the gibbon at one end and man at the other. In our original simplicity we expected, as we traced man backwards in time, that we should

encounter a graded series of fossil forms—a series which would carry him in a straight line towards an anthropoid ancestor. We should never have made this initial mistake if we had remembered that the guide to the world of the past is the world of the present In our time man is represented not by one but by many and diverse races—black, brown, yellow, and white, some of these are rapidly expanding, others are as rapidly disappearing Our searches have shown that in remote times the world was peopled, sparsely it is true, with races showing even a greater diversity than those of to-day, and that already the same process of replacement was at work. To unravel man's pedigree, we have to thread our way, not along the links of a chain, but through the meshes of a complicated network.

#### THE DIVERSITY OF FORM IN ANCIENT TIMES

We made another mistake Seeing that in our search for man's ancestry we expected to reach an age when the beings we should have to deal with would be simian rather than human, we ought to have marked the conditions which prevail amongst living anthropoid apes. We ought to have been prepared to find, as we approached a distant point in the geological horizon, that the forms encountered would be as widely different as are the gorilla, chimpanzee, and orang, and confined, as these great anthropoids now are, to limited parts of the earth's surface. That is what we are now realising, as we go backwards in time we discover that mankind becomes broken up, not into separate races as in the world of to-day, but into numerous and separate species. When we go into a still more remote past they become so unlike that we have to regard them not as belonging to separate species but different genera It is amongst this welter of extinct fossil forms which strew the ancient world that we have to trace the zigzag line of man's descent. Do you wonder we sometimes falter and follow false clues 2

#### DISCORDANT EVOLUTION

We committed a still further blunder when we set out on the search for man's ancestry · indeed, some of us are still making it. We expected that man's evolution would pursue not only an orderly file of stages but that every part of his body—skull, brain, jaws, teeth, skin, body, arms, and legs—would at each stage become a little less ape-like, a little more man-like. Our searches have shown us that man's evolution has not proceeded in this orderly manner. In some extinct races, while one part of the body has moved forwards another part

has lagged behind. Let me illustrate this point because it is important. We now know that, as Darwin sat in his study at Down, there lay hidden at Piltdown, in Sussex, not thirty miles distant from him, sealed up in a bed of gravel, a fossil human skull and jaw. In 1912, thirty years after Darwin's death, Mr. Charles Dawson discovered this skull and my friend Sir Arthur Smith Woodward described it, and rightly recognised that skull and jaw were parts of the same individual, and that this individual had lived, as was determined by geological and other evidence, in the opening phase of the Pleistocene period We may confidently presume that this individual was representative of the people who inhabited England at this remote The skull, although deeply mineralised and thick-walled, might well have been the rude forerunner of a modern skull, but the lower law was so ape-like that some experts denied that it went with the human fossil skull at all, and supposed it to be the lower law of some extinct kind of chimpanzee.

This mistake would never have been made if those concerned had studied the comparative anatomy of anthropoid apes Such a study would have prepared them to meet with the discordances of evolution The same irregularity in the progression of parts is evident in the anatomy of Pithecanthropus, the oldest and most primitive form of humanity so far discovered. The thigh-bone might easily be that of modern man, the skull-cap that of an ape, but the brain within that cap, as we now know, had passed well beyond an anthropoid status. If merely a lower jaw had been found at Piltdown, an ancient Englishman would have been wrongly labelled 'Higher anthropoid ape'; if only the thigh-bone of Pithecanthropus had come to light in Java, then an ancient Javanese, almost deserving the title of anthropoid, would have passed muster as a man.

# BLANKS STILL REMAIN IN THE GEOLOGICAL RECORD.

Such examples illustrate the difficulties and dangers which beset the task of unravelling man's ancestry. There are other difficulties; there still remain great blanks in the geological record of man's evolution. As our search proceeds these blanks will be filled in, but in the meantime let us note their nature and their extent. By the discovery of fossil remains we have followed man backwards to the close of the Pliocene—a period which endured at least for a quarter of a million years, but we have not yet succeeded in tracing him through this period. It is true that we have found fossil teeth

in Pliocene deposits which may be those of an apelike man or of a man-like ape, until we find other parts of their bodies we cannot decide When we pass into the still older Miocene period—one which was certainly twice as long as the Phocene—we are in the hevday of anthropoid history. Thanks to the labours of Dr. Guy E. Pılgrim, of the Indian Geological Survey, we know already a dozen different kinds of great anthropoids which lived in Himalayan jungles during middle and later Miocene times, we know of at least three other kinds of great anthropoids which lived in the contemporary jungles of Europe Unfortunately we have found as yet only the most resistant parts of their bodiesteeth and fragments of jaw Do some of these fragments represent a human ancestor? We cannot decide until a lucky chance brings to light a limbbone or a piece of skull, but no one can compare the teeth of these Miocene anthropoids with those of primitive man, as has been done so thoroughly by Dr. William K Gregory, and escape the conviction that in the dentitions of the extinct anthropoids of the Miocene jungles we have the ancestral forms of human teeth.

#### DATE OF MAN'S EMERGENCE.

It is useless to go to strata still older than the Miocene in search of man's emergence; in such strata we have found only fossil traces of emerging anthropoids. All the evidence now at our disposal supports the conclusion that man has arisen, as Lamarck and Darwin suspected, from an anthropoid ape not higher in the zoological scale than a chimpanzee, and that the date at which human and anthropoid lines of descent began to diverge lies near the beginning of the Miocene period. On our modest scale of reckoning, that gives man the respectable antiquity of about one million years.

#### PROOFS OF OUR ANTHROPOID ANCESTRY.

Our geological search, which I have summarised all too briefly, has not produced so far the final and conclusive evidence of man's anthropoid origin; we have not found as yet the human image emerging from its anthropoid encasement. Why, then, do modern anthropoid encasement. Why, then, do modern anthropologists share the conviction that there has been an anthropoid stage in our ancestry? They are no more blind than you are to the degree of difference which separates man and ape in structure, in appearance, and in behaviour I must touch on the sources of this conviction only in a passing manner. Early in the present century, Prof. G. H. F. Nuttall, of the University of Cambridge, discovered a trustworthy and exact method

of determining the affinity of one species of animal to another by comparing the reactions of their blood. He found that the blood of man and that of the great anthropoid apes gave almost the same reaction Bacteriologists find that the living anthropoid body possesses almost the same susceptibilities to infections, and manifests the same reactions, as does the body of man So alike are the brains of man and anthropoid in their structural organisation that surgeons and physiologists transfer experimental observations from the one to the other When the human embryo establishes itself in the womb it throws out structures of a most complex nature to effect a connexion with the maternal We now know that exactly the same elaborate processes occur in the anthropoid womb and in no other. We find the same vestigial structures — the same 'evolutionary post-marks'— in the bodies of man and anthropoid The anthropoid mother fondles, nurses, and suckles her young in the human manner This is but a tithe of the striking and intimate points in which man resembles the anthropoid ape. In what other way can such a myriad of coincidences be explained except by presuming a common ancestry for both?

#### THE EVOLUTION OF MAN'S BRAIN.

The crucial chapters in Darwin's "Descent of\_ Man " are those in which he seeks to give a historical account of the rise of man's brain and of the varied functions which that organ subserves How do these chapters stand to-day? Darwin was not a professional anatomist and therefore accepted Huxley's statement that there was no structure in the human brain that was not already present in that of the anthropoid In Huxley's opinion the human brain was but a richly annotated edition of the simpler and older anthropoid book, and that this edition, in turn, was but the expanded issue of the still older original primate publication Since 7 this statement was made thousands of anatomists and physiologists have studied and compared the brain of man and ape; only a few months ago, Prof. G. Elliot Smith summarised the result of this intensive inquiry as follows. "No structure found in the brain of an ape is lacking in the human brain, and, on the other hand, the human brain reveals no formation of any sort that is not present in the brain of the gorilla or chimpanzee . . . The only distinctive feature of the human brain is a quantitative one." The difference is only quantitative but its importance cannot be exaggerated. In the anthropoid brain are to be recognised all those parts which have become so enormous in the human brain. It

is the expansion of just those parts which have given man his powers of feeling, understanding, acting, speaking, and learning

#### THE EVIDENCE OF PSYCHOLOGY.

Darwin himself approached this problem not as an anatomist but as a psychologist, and after many years of painstaking and exact observation, succeeded in convincing himself that, immeasurable as are the differences between the mentality of man and ape, they are of degree, not of kind. Prolonged researches made by modern psychologists have but verified and extended Darwin's conclusions. No matter what line of evidence we select to follow—evidence gathered by anatomists, by embryologists, by physiologists, or by psychologists—we reach the conviction that man's brain has been evolved from that of an anthropoid ape and that in the process no new structure has been introduced and no new or strange faculty interpolated.

#### UNEXPLAINED PROBLEMS.

In these days our knowledge of the elaborate architecture and delicate machinery of the human brain makes rapid progress, but I should mislead if I suggested that finality is in sight. Far from it, our inquiries are but begun There is so much we Will the day ever come do not yet understand when we can explain why the brain of man has made such great progress while that of his cousin the gorilla has fallen so far behind? Can we explain why inherited ability falls to one family and not to another, or why, in the matter of cerebral endowment, one race of mankind has fared so much better than another? We have as yet no explanation to offer, but an observation made twenty years ago by one on whom Nature has showered great gifts—a former president of this Association and the doyen of British zoologists—Sir E Ray Lankester deserves quotation in this connexion. "The leading feature in the development and separation of Man from other animals is undoubtedly the relative enormous size of the brain in Man and the corresponding increase in its activities and capacity is a striking fact that it was not in the ancestors of Man alone that this increase in the size of the brain took place at this same period -the Miocene. Other great mammals of the early Tertiary period were in the same case." When primates made their first appearance in geological records, they were, one and all, small-brained. We have to recognise that the tendency to increase of brain, which culminated in the production of the human organ, was not confined to man's ancestry but appeared in diverse branches of the mammalian stock at a corresponding period of the earth's history.

# DARWIN'S CONCEPTION OF EVOLUTION ILLUSTRATED.

I have spoken of Darwin as a historian. To describe events and to give the order of their occurrence is the easier part of a historian's task; his real difficulties begin when he seeks to interpret the happenings of history, to detect the causes which produced them, and explain why one event follows as a direct sequel to another. Up to this point, we have been considering only the materials for man's history, and placing them, so far as our scanty information allows, in the order of their sequence, but now we have to seek out the biological processes and controlling influences which have shaped the evolutionary histories of man and ape.

The evolution of new types of man or of ape is one thing, and the evolution of new types of motor-cars is another, yet for the purposes of clear thinking it will repay us to use the one example to illustrate the other. In the evolution of motor vehicles Darwin's law of selection has prevailed; there has been severe competition and the types which have answered best to the needs and tastes of the public have survived. The public has selected on two grounds-first for utility, thus illustrating Darwin's law of natural selection, and secondly because of appearance's sake, for, as most people know, a new car has to satisfy not only the utilitarian demands of its prospective master but also the æsthetic tastes of its prospective mistress, therein illustrating Darwin's second law—the law of sexual selection. That selection, both utilitarian and æsthetic, is producing an effect on modern races of mankind and in surviving kinds of ape, as Darwin supposed, cannot well be questioned. In recent centuries the inter-racial competition amongst men for the arable lands of the world is keener than in any known period of human history.

#### THE PRODUCTION OF NEW TYPES.

The public has selected its favoured types of car, but it has had no direct hand in designing and producing modifications and improvements which have appeared year after year. To understand how such modifications are produced the inquirer must enter a factory and not only watch artisans shaping and fitting parts together but also visit the designer's office. In this way an inquirer will obtain a glimpse of the machinery concerned in the evolution of motor-cars. If we are to understand the machinery which underlies the evolution of man and of ape, we

have to enter the 'factories' where they are produced-look within the womb and see the ovum being transferred into an embryo, the embryo into a fœtus, and the fœtus into a babe After birth we may note infancy passing into childhood, childhood into adolescence, adolescence into maturity, and maturity into old age Merely to register the stages of change is not enough, to understand the controlling machinery we have to search out and uncover the processes which are at work within developing and growing things and the influences which co-ordinate and control all the processes of development and of growth. When we have discovered the machinery of development and of growth we shall also know the machinery of evolution, for they are the same.

#### MACHINE AND ANIMAL EVOLUTION CONTRASTED

If the simile I have used would sound strange in Darwin's ear, could he hear it, the underlying meaning would be familiar to him. Over and over again he declared that he did not know how 'variations' were produced, favourable or otherwise; nor could he have known, for in his time hormones were undreamt of and experimental embryology scarcely born. With these recent discoveries, new vistas opened up for students of evolution. The moment we begin to work out the simile I have used and compare the evolutionary machinery in a motor factory with that which regulates the development of an embryo within the womb, we realise how different the two processes are.

Let us imagine for a moment what changes would be necessary were we to introduce 'embryological processes' into a car factory. We have to conceive a workshop teeming with clustering swarms of microscopic artisans, mere specks of living matter. In one end of this factory we find swarms busy with cylinders, and as we pass along we note every part of a car in process of manufacture, each part being the business of a particular brigade of microscopic workmen. There is no apprenticeship in this factory: every employee is born, just as a hive-bee is, with his skill already fully developed. No plans or patterns are supplied; every workman has the needed design in his head from birth neither manager, overseer, nor foreman to direct and co-ordinate the activities of the vast artisan armies. And yet if parts are to fit when assembled, if pinions are to mesh and engines run smoothly, there must be some method of co-ordination It has to be a method plastic enough to permit difficulties to be overcome when such are encountered and to permit the introduction of advantageous

modifications when these are needed. A modern works manager would be hard put to were he asked to devise an automatic system of control for such a factory, yet it is just such a system that we are a now obtaining glimpses of in the living workshops of Nature.

#### THE MACHINERY OF DEVELOPMENT.

I have employed a crude simile to give the lay mind an inkling of what happens in that 'factory' where the most complicated of machines are forged —the human body and brain The fertilised ovum divides and redivides, one brood of microscopic living units succeeds another, and as each is produced the units group themselves to form the 'parts' of an embryo Each 'part' is a living society, the embryo is a huge congeries of interdependent societies. How are their respective needs regulated, their freedoms protected, and their manœuvres timed? Experimental embryologists have begun to explore and discover the machinery of regulation We know enough to realise that it will take many generations of investigators to work over the great and new field which is thus opening up. When this is done we shall be m a better position to discuss the cause of 'variation' and the machinery of evolution.

#### THE MACHINERY OF GROWTH.

If we know only a little concerning the system of government which prevails in the developing embryo, we can claim that the system which prevails in the growing body, as it passes from infancy to maturity, is becoming better known to us every year. The influence of the sex glands on the growth of the body has been known since ancient times; their removal in youth leads to a transformation in the growth of every part of the body, altering at the same time the reactions and temperament of the brain. In more recent years medical men have observed that characteristic alterations in the appearance and constitution of the human body can be produced by the action of other glands—the pituitary, thyroid, parathyroid, and adrenals.

Under the disorderly action of one or other of these glands individuals may, in the course of a few years, take on so changed an appearance that the differences between them and their fellows become as great as, or even greater than, those which separate one race of mankind from another. The physical characters which are thus altered are just those which mark one race off from another. How such effects are produced we did not know until 1904, when the late Prof. E. H. Starling, a leader amongst the great physiologists of our time, laid bare an

ancient and fundamental law in the living animal body—his law of hormones. I have pictured the body of a growing child as an immense society made up of myriads of microscopic living units, ever increasing in numbers. One of the ways—probably the oldest and most important way—in which the activities of the communities of the body are coordinated and regulated is by the postal system discovered by Starling, wherein the missives are hormones—chemical substances in ultra-microscopic amounts, despatched from one community to another in the circulating blood. Clearly the discovery of this ancient and intricate system opens up fresh vistas to the student of man's evolution

How Darwin would have welcomed this discovery! It would have given him a rational explanation to so many of his unsolved puzzles, including that of 'correlated variations.' Nor can I in this connexion forbear to mention the name of one who presided so ably over the affairs of this Association fifteen years ago-Sir E Sharpey-Schafer was the pioneer who opened up this field of investigation and has done more than anyone to place our knowledge of the nature and action of the

glands of internal secretion on a precise basis of With such sources of experimental observation knowledge being ever extended, and others of great importance, such as the study of heredity, which have been left unmentioned, we are justified in the hope that man will be able in due time not only to write his own history but also to explain how and why events took the course they did

In a brief hour I have attempted to answer a question of momentous importance to all of us-What is man's origin? Was Darwin right when he said that man, under the action of biological forces which can be observed and measured, has been raised from a place amongst anthropoid apes to that which he now occupies? The answer is Yes! and in returning this verdict I speak but as foreman of the jury—a jury which has been empanelled from men who have devoted a lifetime to weighing the evidence. To the best of my ability I have avoided, in laying before you the evidence on which our verdict was found, the rôle of special pleader, being content to follow Darwin's own example—Let the truth speak for

#### Scientific Problems and Aspects.

SUMMARIES OF ADDRESSES OF PRESIDENTS OF SECTIONS.1

OUTSTANDING PROBLEMS OF RELATIVITY.

IN his presidential address to Section A (Mathematics and Physical C. matics and Physical Sciences), Prof. E. T. Whittaker refers first to the remark made by FitzGerald in 1894 that "Gravity is probably due to a change of structure of the æther, produced by the presence of matter," and discusses the relation of Fitz(lerald's views to Einstein's theory of gravitation He then describes some of the consequences of general relativity, other than the well-known bending of light-rays by the sun and gravitational shift of spectral lines follow on the number of unsolved problems of the statical type, for which only the ordinary threedimensional analysis is required, and which may therefore be attempted by those investigators who distrust their own powers of doing research in four dimensions. Reference is also made to connexions with the new wave-mechanics

Prof. Whittaker then examines successively the relation of geometry to physics, and the place of electromagnetic phenomena in general relativitytheory, referring to the non-Riemannian geometries

which have been suggested by Weyl, Eddington, Schouten, Wirtinger, and others.

This is followed by an inquiry into the axiomatics of the subject. The usual way of introducing relativity is to talk about measuring-rods and clocks, but Prof. Whittaker disapproves of this, and considers that the notions of 'length of material bodies' and 'time of clocks' are really rather complex notions which should not be introduced into the earlier chapters of axiomatic physics. He begins instead with the tracks of light-rays and of particles in the field, and shows how from them it is possible to construct the quadratic differential form which lies at the basis of the analytical theory, without introducing the notions either of length or of time. The next step is the assertion that the laws of Nature must be represented by equations which are covariantive with respect to this quadratic form with respect to all point-transformations of co-ordinates: after which the development of the theory proceeds in the usual way By this procedure we obtain a geometry which is based entirely on light-rays and paths of particles, leaving open the question whether this is, or is not, identical with the geometry based on rigid measuring-rods The results of the ether-drift experiments of

 $<sup>^1</sup>$  The collected presidential addresses delivered at the meeting are published under the title "The Advancement of Science 1927," at 6s, or may be obtained at the bookstall at Leeds by members for 4s, 6d

D C. Miller at Mount Wilson in 1925, if confirmed, would seem to indicate that the two kinds of geometry are actually different

Prof. Whittaker then discusses the place of minimum-principles in physics. Gravitation acts so as to make the total amount of the curvature of space-time a minimum or, as we may say, gravitation simply represents a continual effort of the universe to straighten itself out. This is general relativity in a single sentence. He then examines the Mach-Einstein doctrine that the metric of space-time is determined wholly by the masses and energy present in the universe, so that space-time cannot exist at all except in so far as it is due to the existence of matter. Finally, reference is made to the De Sitter world and the difficulty of estimating the radius of curvature of the universe.

#### Co-ordination Compounds.

DR N. V. SIDGWICK points out in his presidential address to Section B (Chemistry), how the apparent contradiction between the principles of structural chemistry and the theory by which Werner accounted for the composition and properties of his co-ordination compounds was resolved by means of the electronic conception of valency. co-ordinate link is clearly from its behaviour a form of covalency (non-ionised link), consisting in the sharing of a pair of electrons between the two linked atoms; but whereas in the normal covalency one of the two electrons is derived from each atom. and so the number of links formed depends on the periodic group to which the atom belongs, in the co-ordinate valency both electrons are derived from one atom, which removes this limitation, and the maximum covalency or co-ordination number is the number of pairs of electrons in the maximum valency group.

The formation of a co-ordinate link thus requires the presence (a) of an atom (the donor) with two unshared valency electrons to lend, and (b) of another atom (the acceptor) capable of taking them up. The link so formed is less stable than an ordinary covalency, owing to the greater stability of the products of its rupture, and it also communicates a dipole character to the molecule (the donor having something of a positive and the acceptor something of a negative charge), which leads to an increase in the dielectric constant and a diminution of the volatility. It is by the formation of these links that liquids become associated, and accordingly we always find in the molecule of an associated liquid a donor and an acceptor atom, in the commonest case of the

hydroxyl group, the oxygen of course is the donor and the hydrogen the acceptor. This explains the anomalous position of such compounds as amines and ethers, which behave like associated liquids in some ways but not in others: they contain donors (the nitrogen or the oxygen) but no acceptors, and hence cannot associate with themselves or with non-associated substances, but can do so with associated substances, because the latter contain the requisite acceptor atoms

The occurrence of co-ordination compounds is thus by no means confined to the Wernerian complexes, but is widely distributed throughout organic as well as inorganic chemistry essential to recognise the importance of this factor in chemical reactions, especially in relation to the modern intensive study of reactivity in organic compounds The unique position of carbon, on which the very existence of organic chemistry depends, can only be understood by reference to the theory of co-ordination its mertness in its saturated compounds (to which the number and variety of these compounds is largely due) depends on the fact that the quadrivalent carbon atom, with a completely shared octet incapable of further expansion, can act neither as donor nor as acceptor

The further development of our knowledge of the influence of co-ordination on reactivity involves in particular the investigation (1) of the effect of other atoms in the molecule on the tendency of an atom to exert its donor or acceptor properties—on its power of forming co-ordinate links—and (2) of the extent to which the formation of co-ordination compounds is an intermediate stage in chemical reactions

#### TERTIARY VOLCANIC ACTIVITY IN BRITAIN.

DR HERBERT H THOMAS'S presidential address to Section C (Geology) is concerned with the British. Tertiary centres of intrusion, more particularly with the plutome and hypabyssal rocks. Local subsidence is the chief factor in the determination of the sites of the major intrusions, which subsidence has allowed the uprise of magma from the great intercrustal basin that supplied the plateau-basalts. The ring-dyke and the stock are the dominant forms adopted by the main intrusive bodies and the two are closely related in origin. Laccolites in the true sense are practically unrepresented, as might be expected in regions that have been affected by tensional rather than compressional forces.

The sequence of events as established by recent

work in the respective centres, and the mutual relations of contiguous intrusive masses, are dis-In unravelling the structure of an igneous complex, emphasis is laid on the importance of screens—those narrow masses of older rocks that completely or partially separate otherwise contiguous intrusions of ring-dyke type. As regards the origin of the various rock-types, the view is taken that they are all derived from a magma of basaltic composition by a process of differentiation which is primarily dependent on the separation of crystalline phases In agreement with Dr. Harker, however, Dr Thomas holds that the general order of intrusion, that is, from basic to acid, could not be maintained without the remelting of an already differentiated density-stratified, or completely Contamination has played no solid magma appreciable part in modifying either the primary or subsequent magmas, and no variations of rocktype among the major intrusive bodies can be attributed to this cause.

#### ANCIENT HISTORY OF ANIMALS.

In his presidential address to Section D (Zoology), after discussing indications of a pre-Cambrian cataclysm, Dr. Bidder considers the conditions of originating life, and suggests that protein adds to itself rhythmically, alternately accumulating energy from the environment and expending it on the formation of a new molecule. This rhythm of energy would be accompanied by a rhythmical expansion and contraction of volume. Evolution of the flagellate consisted in the formation of a permanent filament of protoplasm characterised by having one side more gelated than the other side. Thus the rhythmic expansion in volume caused a rhythmic convexity of the more extensible side, followed by an elastic counterstroke at the moment of synthesis and contraction The rhythm of storage of energy alternating with synthesis has never been lost, and is the foundation of our sense of time and of the phenomena of age and senile death.

The mucilaginous exudation of flagellates enables their longitudinal fission to produce sheets of coherent cells, often curved until they form closed 'hilospheres.' In such a closed sphere exudation cannot escape from the central cavity, so that if the cellular envelope be permeable, the tension of its walls and of its surface are opposed by the osmotic pressure of its contents. Should the cells of a hilosphere or blastosphere at any time withdraw salts, proteins, or sugars from the gelatinous interior, so as to make it hypotonic

to the external water, water will pass out and invagination will take place.

In certain strains of flagellates the cells of the envelope, behaving as do Metazoan cells in vitro, proliferated cells into the internal jelly, which thus became capable of transformation into the inter-epithelial parenchym of coelenterates and true sponges, the mesenchym of larvæ and the tissues of the higher Metazoa. This tendency is shown in Proterospongia, but is not usual in colonial choano-flagellates, and it is not shown in hexactinellid sponges, which must therefore be distinguished as Porifera nuda from the Porifera vera the collar-cells of which are based on jelly. The Clavulida, Desmacidonida, and Renierida show triaxon symmetry in their spicules (cf. NATURE, Feb 28, 1925, vol 115, p 298), and are probably descended from Hexactmellida They may be grouped together (probably with the Axinellida) as the Orthogonida. The Portfera vera include Tetraxonida s.s., Ceratosa, and Calcarea, from these last the Enterozoa may be descended.

Sponges are multicellular organisms specially adapted to bring to each flagellate cell a number of minute organic particles suitable for intracellular digestion, and to exclude larger fragments. In no sponge can the sponge's current carry a body larger than a human blood-corpuscle into the flagellate chamber, and in most the entrance pores of the chambers will not admit a particle one-third of this diameter. Therefore sponges are older than Enterozoa, which are evolved to digest large fragments, and must have originated after there existed cellular aggregates large enough to require a stomach to attack them. If Enterozoa be descended from sponges, they may both still be united in the kingdom Animalia; if they are not so descended the sponges must be recognised as a third kingdom of multicellular organisms, the Microphaga, specialised for the intracellular digestion of living organisms less than  $5\mu$  in diameter

#### SOME PROBLEMS OF POLAR GEOGRAPHY.

Dr. R. N. Rudmose Brown, in his address to Section E (Geography), deals first with some problems in the physical geography of polar regions. The attainment of the poles has not put an end to the need for exploration, but has rather given an opportunity for work in the future being concentrated on specific problems. In the Antarctic, the two great problems are the discovery of the outline of the continent, the existence of which is still based on circumstantial evidence, and the elucidation of its structure and relations to the

other southern continents. The relationships of the contrasted structures of Victoria and Graham Lands are discussed at length Further problems of importance awaiting solution are the peculiar Antarctic blizzards and the general circulation of air over the continent, especially with reference to the alimentation of the ice-sheet

In Arctic regions there are no pioneer problems of equal magnitude, and though no extensive land is at all likely to be discovered, there is the possibility of several reports of islands having some foundation in fact. These are discussed in full. Of more importance is the oceanographical exploration of the Arctic basin and the explanation of its origin as an earth feature. The circulation of Arctic waters and the distribution and fluctuation in amount of ice discharged into the Atlantic are problems with a practical bearing on the weather of the British Isles.

In discussing the methods of exploration, Dr Rudmose Brown sees little value in the aeroplane for the detailed scientific work that is now required in polar exploration, except in the survey of difficult country lying within easy reach of a base accessible by sea transport and provided with good landing places. Amundsen's daring flight across the Arctic Ocean had few important geographical results. In the Antarctic, where much pioneer work has still to be done, aeroplane flights may be of some value, but a forced landing would probably spell disaster

The last part of the address is concerned with a discussion of the possibility of settlement and colonisation in Arctic lands. This entails an examination of Mr. V. Stefansson's glowing picture of the future of the Arctic prairies of Canada, and the fate of the old Norse colonies in Greenland. As pressure on the world's food resources becomes greater, pasture land in temperate lands will become scarce. Then the value of Arctic prairies for reindeer and musk-ox will be realised. Herein lies the probability of a gradual invasion by the white races of the outer rim of the Arctic as the native races of Siberia and northern Canada die out before the flowing tide of civilisation. Climate offers no real impediment to Arctic settlement.

#### ORGANISATION IN INDUSTRY.

Prof. D. H. Macgregor's address to Section F (Economic Science and Statistics) on "Rationalisation of Industry" consists of a review of the questions raised by the claims of highly organised industrial combinations to control and steady the evolution of industry. Attention is first directed to the change of opinion which has taken place in the post-War period as regards such combinations, which were regarded with much less favour before the War. The creation of such great structures as the European steel cartel has reacted on the views held in each country, since national organisation is a condition of international agreements of this kind.

The conception of rationalisation is presented as one which makes in industry for the application of the idea of government, and of the leadership of those most qualified to govern. The 'cartel,' the 'trust,' and the 'concern' show different aspects of this conception. The idea of the government of an industry as a whole, as distinct from the less organised relations of competitive producers, is borrowed from political affairs, and the question, how far it is applicable to the field of industry should be discussed by bringing also into the argument such other types of government as the ecclesiastical and the military

Industry is not alone in not having been able to apply the political type of administration, the sphere of, for example, authority being greater in other non-political spheres than in industry. Some ideas are common to the conception of government anywhere, such as the completest range of control, and the control of what hes on each side of the main interest—and these appear in industry as the tendency toward monopoly, and toward the vertical union of successive stages of production. But the special conditions of the industrial sphere, private liability and risk, are unique

The organisation of 'combines' shows that many advantages could follow in respect both of the technical evolution of capitalism, and its relation to labour. But what is most rational in the way of higher organisation in industry is to be found rather in a proper balance, something being sacrificed from the unity of a complete government on one hand, and on the other hand from the 'Ricardian rationalisation' which works out through the adjustment of success and failure. Industry is not to be subsumed simply under the conceptions of government which are valid elsewhere, but must-find out what degree of unity in administration in consonant with its unique conditions.

#### DISCOVERY AND INVENTION

SIR JAMES B HENDERSON, in his presidential address to Section ( Engineering), deals with "Invention as a Link in Scientific and Economic Progress" Discovery and invention are so closely allied that they are frequently confused, and in common speech the two words are often used synonymously. No clear distinction can be drawn between them except in such general terms as that discovery begins and ends as a mental conception forming an addition to man's abstract knowledge. while invention, although also a mental conception in its origin, is essentially material, masmuch has it is a conception of some practical application knowledge Discovery and invention bear therefore towards each other more or less the same relation as exists between theory and practice, between the abstract and the concrete

Both are alike, in that although possibly the result of an instantaneous flash of inspiration, or possibly of an accident, or it may be, the result of long and tedious study, great discoveries and great inventions can seldom be considered complete until much time and effort have been spent on their confirmation or development. This latter period of their history generally demands also the expenditure of large sums of money, so that we find in discovery, invention, and finance, a union of three factors allied in the service of man.

Invention, considered by itself as a link in progress, is a peculiar combination of an exact science, such as engineering, physics, or chemistry, with a historical science, like the science of war or of economics. The latter are studied as sciences, though based in no foundation of physical laws The science of war is studied historically from records of the tactics, strategy, successes, or failures of old campaigns, such records being kept with meticulous care in official records for the benefit of the soldiers of to-day But in the science of invention no such records exist, with the result that in the war between the inventor and Nature the same mistakes recur again and again, and many an invention fails from lack of any historical record or intelligence service such as guard the soldier against repetition of the mistakes committed by other generals of the past In other words, the inventor starts from scratch, yet there must be, or must at some time have been, an enormous volume of technical knowledge which, were it only available, would aid greatly in the rapid development of his invention and would possibly turn some of the failures into successes Is there no way to bring this accumulated knowledge to light? Much of it is necessarily lost because those who possessed it have died without leaving any record of their knowledge. But can we not start now to remedy this defect and to prevent its perpetuation?

Much could be done if science could be taught historically in our schools and colleges this the great impediment is time. So much has already to be crowded into the short course of scientific study that no time is left for the study of the history of a science. Possibly something could be done by legislation through alteration of the Patent Acts to bring the history of an invention, with all its difficulties and their conquest, within the description of the invention published in the patent specification. This would necessitate discrimination between minor inventions which can be rapidly and easily developed, and the major inventions which form the milestones in scientific progress. The development of these cannot possibly be achieved, or the difficulties overcome, within the short period of nine months within which a supposedly complete description of the finished invention has to be filed. A third remedy lies in the hands of the British Association and other kindred bodies, to whom it is open to invite inventors to contribute a historical record of their inventions, whether successful or unsuccessful, and particularly a record of the difficulties which they encountered in the process of development. Such records, which could be published in the proceedings of the technical societies at a time selected by the authors, would furnish a nucleus of an invaluable library of a kind which does not exist to-day, and would be of incalculable assistance to the inventor and the scientific worker of the future

#### THE ENGLISHMAN OF THE FUTURE

PROF F. G PARSONS, in his presidential address to Section H (Anthropology), deals with

the knowledge which he has gained of the way in which the Englishman has changed during the centuries, and, considering these changes, he suggests their probable effect in building up the Englishman of the future.

With regard to height, the well-nourished Englishman of to-day averages 5 ft 9 in.; and, because he has done so steadily for the last twenty years, it is thought that this height is the limit which English males will reach With English women, on the other hand, height seems to be increasing year by year, and there is no reason therefore to think that the present average of 5 ft 5 m for women of the well-nourished classes will not be passed by two or more inches regard to colour, when the statistics of to-day are contrasted with those left us by Dr. Beddoe, sixty years since, the present observer has to admit that he finds no sign of darkening of either hair or eye colour, but that, in every case, the change, though slight, is on the side of fairness. In these two factors of colour and height, therefore, there is reason to think that, so far from the Nordic characteristics of the English people disappearing, they seem to be increasing

In dealing with head shape, it is important to take into account the head height as well as the cephalic index, which alone is not sufficient to indicate what is happening. The length, breadth, and height of the head can be expressed in terms of the sum of all three, and the variations of these ratios, from the earliest Neolithic times to those of the present day, can be demonstrated. One of the most striking facts brought out by this method is that during the last two centuries the English skull has been increasing very markedly in height, even in the poorly educated classes of the community, while in the more highly educated, which have been influenced most by modern hygiene, the increase is really startling, and the head height is much greater than that which any of the races from which the modern Englishman is derived can show. The inference is that environment, rather than heredity, is influencing the head shape, and that the Englishman of the future will have a head quite different in shape from that of any of the ancestral races from which he is descended. With the shape of the head, of course, that of the brain is changing too, and this cannot be without its effect upon the mental characteristics of the Englishman of the future

#### THE DEVELOPMENT OF HUMAN PHYSIOLOGY

The last fifty years have witnessed the great extension of the method of physiological investigation by means of direct experimentation on animals, a method which may be termed the analytical method since the organism is treated as a series of systems which, though but parts of a whole, are yet capable of being regarded within limits as independent Valuable though this method has proved, and will continue to prove in the future, Dr C. G Douglas, in his presidential address to Section I (Physiology), points out that we must recognise that it has in

reality definite limitations, and if we are to understand life we must ultimately adopt methods of investigation which do not interfere with the normality of the organism or its natural powers of self-maintenance

In the study of normal physiology, man is in many instances a more advantageous subject of investigation than are the lower animals, because we can ensure the maintenance of any degree or type of natural activity that we may desire, we can obtain the co-operation of the subject, and we can learn his subjective impressions. This claim can be justified by a review of the experimental work which has already been done on the human subject in many branches of physiology; for example, in the study of the general energy output under different conditions of normal activity, of the regulation of the respiration and circulation, of the function of the kidneys and of the alimentary canal, while we owe much m other fields to m-, vestigations undertaken primarily in the cause of clinical medicine The outstanding contributions to knowledge which we owe to human physiology are the quantitative changes of organ activity associated with normal life, the close functional linkage of the different organs, and the power of adaptation to altered circumstances.

We have learnt something of what really characterises normal life, and we have been put in a better position to make use of the information obtained by the analytical method of investigation of the lower animals, which by itself affords, as a rule, evidence of potentialities rather than actual-

ities.

The development of human physiology is already sufficient to justify greater prominence being given to this subject in our teaching of physiology, and this is especially true of practical courses of instruction. Many students only take a course of elementary physiology as a preliminary to the study of medicine, but it is not difficult to incorporate even in an elementary course simple experiments in human physiology which, by allowing the student to appreciate something of what happens in his own person in the course of everyday life, will awaken his interest and curiosity, and by giving him a guiding line of thought will help him to grasp more readily the significance of what he reads. Unless the student can gain some real conception of the way in which physiology is helping to elucidate the phenomena which characterise normal life, there is a risk that a gulf, for which there can be no justification, will deepen between physiology and medicine.

#### MENTAL UNITY AND MENTAL DISSOCIATION.

It is significant that the problem of unity and dissociation occurs in many forms in current physical, physiological and psychological spheres. Even in psychology alone, various doctrines have caused controversies as to the answer to be given to the question. What is unitary and what is multiple? Thus the Gestalt psychologists stress the unity of a presentation or pattern. Another

notable instance is the question of the purity c 'general mental energy 'as a mental content

In abnormal psychology the problem presents characteristic form Dr W. Brown, in his presi dential address to Section J (Psychology), points out that Pierre Janet and Morton Prince in the hypnotic period of psycho-pathology developed the concept of mental dissociation, and a char acteristic feature of this period is the frequence with which cases of multiple personality wer discovered Dissociation, for Janet, is the fundamental and all-important feature of neurot disorders It is true that in the writings of Free and Jung the word 'dissociation' seldom occur its place being largely taken by the term 'repre But it is characteristic of Dr. Brown's vie that both unity and dissociation are regarded a aspects of the normal nund; both are ultimat In his latest book, "Mind and Personality" Dr. Brown points out that recent discussions : personality stress the multiplicity—" looking for unity as a result of interaction between the mar, instead of regarding the unity as somethin ultimate '' He admits that the unity of the developed adult mind is to a great extent ai acquired unity, but holds not only that ultimately we are multiple as well as unitary, but also than the feeling of unity is present at every moment of consciousness

Lest such a view be regarded as an insignificant platitude, it may be noted that cases of multiple personality are no longer on record among the psycho-analysts of to-day, who have replaced hypnosis by deep analysis, or autognosis as Deserving Brown prefers to call it, the reason being that the hypnotic method tended to produce multiplicity, whereas autognosis is a process of unification. There is actual development of the mind going on during the process towards the normal and the unitary. Any dissociation that is encouraged by the method is a normal dissociation, any dissociation that is overcome is a pathological dissociation or repression, that is, a dissociation

that is not complete or thoroughgoing.

In an attempt to interpret character and personality along these lines, Dr. Brown is therefore unable to accept McDougall's theory of the self as a system of monads which form a hierarchy, in which there is one dominant monad, the conscious self, and a number of subsidiary monads that are, in a normal mind, adequately subordinated to the chief monad and are in relation to the chief monad through telepathy, but in a case of multiple personality, one of these subsidiary monads may break loose and become insubordinate. (In such highly hypothetical matters differences of opinion are inevitable In many respects, however, Dr Brown is in agreement with McDougall. It no scarcely be said that both hold that a biolo which neglects psychology is incomplete, as unity of the organism becomes more intelligi when we think of it as a mental, and in part, a conscious, unity. The ultimate factor is a purposi general striving, which must be assumed in org to account for the theory of conditioned reflexes

EARLY BEGINNINGS OF PLANT LIFE

For F E. Fritson's address to Section Botany) deals with "Some Aspects of the ent-Day Investigation of Protophyta" A study ne simpler Algæ and holophytic Flagellata is arst importance, since they afford the only crial upon which we can base views of the early nnings of plant-life and the mode of origin of olant-body. The modern outlook with respect nese organisms dates from the distinction some tly years back of the Green (Isokontæ) and thw-green Algæ (Heterokontæ), as phyla originaa from separate flagellate ancestries ores differ in certain morphological features, but a) fundamentally in physiological characteristics ortid-pigments, products of photosynthesis, etc.) n he same basis nine further classes of pigmented o phyta are recognisable, representing as many vationary lines. The old distinction between as and Flagellata is no longer tenable, since Lous classes of the latter (Chrysomonadmeæ, (idinieæ, Cryptomonadineæ) have been shown to Isess true algal representatives It is probable at each series of holophytic Flagellata might ve advanced to algal organisation, although ne (Euglenineæ, Chloromonadineæ) have aparently failed to do so. The acquisition of algal haracteristics (cell-wall, sexuality, etc.) has ensued different levels in the different classes, thus, in he Heterokontæ and Chrysophyceæ the motile Inicells and the palmelloid types are Flagellates, Abulst in the Isokontæ the same forms are ievalently algal.

There is evident a far-going parallelism (homolasy) between the classes of pigmented Proto-hyta. The same types of construction (unicelluter, colonial, filamentous) recur repeatedly and are a part represented by astonishingly similar forms. Evolution has clearly progressed along analogous ines in each class and, except in four (Bacillariales, Pryptophyceæ, Euglenineæ, Chloromonadineæ), has bulminated in the branched filament. The highest Isokontæ (Chætophorales) possess a plant-body differentiated into a system of prostrate threads and a branched projecting system. The same type of thallus is found in the simplest brown and red seaweeds, most of which are nevertheless far more elaborate. The green Algæ thus terminate blindly at the level at which the two great marine

In view, however, of the extreme capacity for morphological elaboration and for adaptation to very diverse habitats (including terrestrial ones) shown by the Isokontæ, a failure to develop further in the direction generally inated by the Phæophyceæ and Rhodophyceæ is conceivable; moreover, their photosynthetica inpment is that characteristic of land-plants, is implies that, approximately at the level of orphological differentiation and stature reached the Isokontæ, the terrestrial habit was adopted ad that the more advanced green Algæ have been cost because they became land-plants. The many analogies that can be traced between Phæophyceæ

and Rhodophyceæ on one hand, and land-plants on the other, are to be regarded as a natural outcome of the general evolutionary trend in the vegetable kingdom. As regards the alternating generations, so characteristic of land-plants, the evidence for or against their occurrence in the higher green Algæ is at present quite inadequate, and parallel cases to that of Pylaiella among the Ectocarpales are perhaps yet to be found in the Chætophorales.

The address concludes with remarks on the methods of investigation of the simpler Algæ. The limitations of pure cultures are discussed and a direct periodic study, especially of the filamentous types, advocated Attention is directed to the extremely backward position of Great Britain as regards fresh water biological stations and the urgent need for the establishment of a well-staffed and properly equipped station on the Norfolk Broads emphasised.

#### BROADENING THE EDUCATIONAL OUTLOOK.

In her presidential address to Section L (Educational Science), the Duchess of Atholl deals with the point emphasised in the recent Report of the Board of Education's Consultative Committee on the Education of the Adolescent, that the wide variations of capacities and gifts among the large number of children in the schools can only be met by a wide variety of courses of instruction.

After briefly reviewing the broadening curriculum, both in school and university the Middle Ages, she points out that it is only within the last twenty or thirty years that there has been established a fairly balanced secondary curriculum in literary and scientific subjects, and that it is not surprising, therefore, that the progress of handwork as an instrument of education has been slow. But handwork, with its appeal to the child's creative interests, can be equally helpful laying the foundations of cultural developments of the child's as reading, writing, and arithmet.

So far as secondary schools are concerned, it was only in 1912 that the Consultative Committee recommended that every secondary school should provide for the teaching of some branch of educational handwork. As regards elementary schools, the same Committee reported in 1905 in favour of schools which would combine a general education with some practical instruction in a course extending up to 15 years of age, while the Education Act of 1918 has made it obligatory on education authorities to provide practical and advanced instruction for older scholars either in central schools and classes or otherwise.

Although the need for a wider curriculum, including practical work, has thus clearly been recognised, the present position can scarcely be regarded as satisfactory. There is still too great a tendency to pass on as many children as possible to the ordinary secondary school where the curriculum, however well adapted for boys and girls of scholastic ability, may be quite unsuited to pupils of another type, leaving school at about 14 or 15

of age. The reasons for the neglect of principal training have been various, but principal pally here has been a failure to appreciate the psychogical issues involved Practical work is one was of securing the interest of the child, and there wan be no intellectual development without internand understanding. This truth does not merch apply to the younger children, as recent psyconogical tests have shown that the need for the conty of curriculum mereases with adolescence. Per curl instruction is not merely desirable for the i backward, in whose case its worth is generally recognised, it is necessary for those chili who have a non-verbal or practical ability which may be quite equal to the normal and yet fall to now itself in the ordinary lessons of school By agoviding an outlet for this practical ability, confidence is gained which reacts with good results on the ordinary school work
Further, it is important to remember that

practical instruction is an element in character training tapping fresh sources of energy and forming a wholesome corrective for the On educational grounds alone, therefore, at the post-primary stage there is need for the greatest variety of courses and for courses

including practical instruction.

Such instruction is also required from the point of view of social and economic welfare. Practical will engender adaptability and will produce

girls who will not regard the clerical ions as the only avenue open to them, but will be ready to take their place in industry and will have the mitiative to avail themselve opportunities offered by our Empire overseas. will further assist in that important part of education-training for lessure; while, in so far as handwork is often co-operative, it will remforce that raining in the team spirit which is inculcated school games and school life generally.

st important task of education in the ruture is to develop new forms of postinstruction which shall not be a mere imitation or rival of the ordinary secondary school, but will offer to every child a chance of developing its special ability as well as of acquiring general culture. Many difficulties have to be faced eachers but if this aim can be kept clearly in view, progress will be sure, and we shall be able so to frame our system of education as to bring to the service of the community in its varying needs rich cutributions of equally varied ability

#### AGENULTURE AND NATIONAL EDUCATION.

SEVERAL aspects of agriculture in its relation to education are discussed in Mr. C. G T. Morison's presidential address to Section M (Agriculture) He deals arst with the provision of technical and vocational training in agriculture, he points out that no system can be regarded as complete which fails to make provision for the instruction of all three partners in the industry, no system can be prompted as satisfactory which is not more com-

pletely utilised than the present. vision of technical education for the landlord and the farmer has been satisfactori, developed, manual worker, upon whose sl. ' ... efficiency of the business more th finds little or no opportunity for

It is suggested that one reason technical education and research full effect upor the agricultural in fact that many farmers and all To obviate this it would be necessary to ensure the something in the nature of general education, university type should 1 available throughout t country districts, so that cultural education application applicat from vocational training, could be continued to much later age than at present. It is hold the before it is possible to make a faller use of th technical instruction which is, or can be provide a it is necessary to arouse the desire for it, forth it is necessary to create and muntain a mo receptive mind

WINE W

The present unsatisfactory condition of the agricultural industry demands some definite polici and this can only be achieved if there is a great understanding of the needs of agriculture b the whole population, urban as well as rure Justification for this widening of agriculture education is to be found in the fundamental in portance to the nation of a flourishing agricultur. In the opinion of certain authorities, the day is no far off when not only Great Britain but also countries hitherto food-exporting will have to consider the framing of a definite national agr cultural policy in the interests of the whole population lation. If Sir Daniel Hall and those who thing with him are right, the time will shortly come whe the demands of an increasing population will make intensification of production inevitable. Thus continued scientific investigation is necessary in order to produce this result will only be realised by that nation which includes some knowledge of agriculture and food production in the natic education of its citizens.

It should be possible by broadening the basis of scientific education to bring it none into touch with the realities of life. This could be achieved by developing, from the most elementary nature study, a conception of scientific training which would meet all the requirements of the ordinary man, and would enable him to have a reasured and informed opinion about the most fundamental of all industries, and the various problems of the food supplies of the modern world food supplies of the modern world As a purely educational and non-vocational study agriculture is a suitable university subject if it be not confined. as hitherto, almost entirely to the sule cophysical science, but developed to include a star of current agricultural conditions throughout the world, and of economic science in its application to periculture The world situation to-day demands formation tion on this subject among educated ; the precarious position of the industry in Circles Pritains, demands a sympathetic understanding. Buth of these demands can only be meaby fuller calucation

## ASTRONOMICAL NOTES.

Comets:

Comet Pons-Winnecke, 24; Comet Notes, 238; Comets, 272; Comet Gale, W. F. Gale, 344, Gale's Comet, H. E. Wood, 419; Detection of Schaumasse's Comet, 562; The Nucleus of Comet Pons-Winnecke, F. Baldet, 741; New Comet, 781; The Return of Encke's Comet, 781; Comets, 816; New Comet, 854; Skjellerup's Comet, 894, 929; The Spectrum of the Comet Pons-Winnecke, 964

Instruments;

The Spectrohelioscope, L. McCrae, 24

Meteors:

The Great Perseid Shower of Meteors, W. F. Denning, 24, A Meteor transits the Sun, A. Stentzel, 201, Meteoric Fireballs, W. F. Denning, 419; The Daylight Fireball of Sept. 7, W. F. Denning, 456; Meteor Shower of Giacobini's Comet, W. F. Denning, 597, Brilliant Meteors on Oct. 17, W. F. Denning, 631; Shower of Large Meteors, W. F. Denning, 705

Observatories:

The Stonyhurst College Observatory, 94; Report of the Royal Observatory, Cape of Good Hope, 381; Norman Lockyer Observatory, Annual Report of the,

Planets:

The Planet Jupiter, W. F. Denning, 166; Variable Rotation of the Earth, Prof. W. de Sitter, 201; Conjunction of Jupiter and Uranus, 272; The Temperature of Mars, Prof. H. N. Russell, 311, The Mass of Venus, Dr. H. Spencer Jones; Dr. J. K. Fotheringham, 311; Venus, H. McEwen, 344; Photometry of the Moon's Surface, A. Markov, 597; The Atmospheres of the Capit Planets, Prof. H. N. The Atmospheres of the Gant Planets, Prof. H. N. Russell, 631; The Transit of Mercury on Nov. 10, 670; Ideal Lunar Landscapes, L. Rudaux, 705; The Transit of Mercury, 741, The Total Lunar Echpse of Dec. 8, 816; Jupiter, B. M. Peck and Petr. T. F. B. Phyllog. 200 Rev. T. E. R. Phillips, 929

Stars:

A Discussion of Stellar Variability, Prof. C. D. Perrine, 166; Spectroscopic Parallaxes of Early Type Stars, D. L. Edwards; Dr. H. C. Woods, 201, Maximum of Mira, 272; An Extremely Massive Multiple Star, Dr. O. Struve, 381; Stars with Bright Iron Lines, Dr. Merrill, 381; A Nova or Variable in Aquila, 419; Exceptional Stars, Prof. H. N. Russell, 419; Rotation of the Galaxy, J. H. Oort, 491; The New Star in Aquila, 491; Observations of the Variable Star Z Herculis, J. Gadomski, 562, The Nebulosity around Nova Aquilæ III., Hubble and Duncan, 705; Discovery of a Nova, 781; Detection of a New Naked-eye Cepheid, 854; The Light Curve of Mira Ceti, 929; Measures of Double Stars, Prof. G. van Biesbroeck, 964; The Schwassmann-Wachmann Nova, Miss Cannon, 964

Sun:

Solar Radiation, Dr. C. G. Abbot, 130; Naked-eye Sunspots, 201; Sky Illumination during the Total Solar Eclipse of June 29, Miss Catherine O. Stevens, 272; Naked-eye Sunspot, 311; Recent Sunspots, 456; The Total Solar Eclipse of June 29, G. Armellini and G. Conti, 491; Dr. H. Kienle, 562; Magnetic 'Storm' and Sunspots, 597; Magnetic Disturbances and Sunspots, 670; Naked-eye Sunspot, 741,

Sunspot Records from Arizona and Californian Trees, A. E. Douglas, R. E. De Lury, 781, Solar Activity during 1926, 854, The Rotation of the Galaxy, Dr. Oort, 894, Occultations, Dr. Innes, 894

Miscellaneous.

Clouds, Prof. E. S. King, 130, Recent Magnetic Disturbance, 166, Tables for Ephemerides in Parabolie Orbits, B. Stromgren, 381; A Spectroscopic Determination of the Aberration Constant, Dr. H Spencer Jones, 456; Meteor Cratei, Arizona, D. M. Barringer, Junr, 456, Tables for Motion in an Ellipse, Dr Innes, 631, The Astrographic Catalogue,

Film: The Mind and the, a Treatise on the Psychological Factors in the Film, G. F. Buckle, 223

Finland: Education in, 425; Ice on the Coast of, 168 Finlayson's Clinical Manual for the Study of Medical Cases The fourth edition, edited by Dr C H. Browning, Dr. E. P Cathcart, and Dr. L Findlay,

revised and augmented, 948
Fireball of Sept 7, The Daylight, W. F. Denning, 456 Fire Resistant Construction, 529

Fish Eggs and Larvæ from the Java Sea, Dr. H. C. Delsman, 492

Fisheries Notices, Nos. 3 to 14, 739

Fishing: Gear of England and Wales, F. M Davis, 382; Industries, Scientific Research in the, M. Holland,

Flame and Combustion: A Egerton; G I. Finch, 694; Prof. W. A. Bone and Dr. D. T A. Townend, 431, 586, 694, 880; Prof. H. E Armstrong, 431, 586, 806 Flat Surfaces, Contact of, F. H. Rolt and H. Barrell, 788 Flexure of Thin Cylindrical Shells and other 'Thin Sections, On the, L. G. Brazier, 137

ts Fractured, Surface Structures of, Dr W. R. Whitney, 14, Worked, at Stone Cross Farm, Luton, Kont, Discovery of, S Turner, 209 Flints

Floras, Local, 763

Florentium or Illinium? Prof. W. A. Noyos, 14 "Flottierende Stationen," Dr. H. C. Redeke, 310

Dielectrics under Stress, Movement in, P. Dunsheath, 364, Mass and Geodesy, General Movements of Rotation of the Heterogeneous, P Dine, 319; Vortices, T. Terada and K. Hattori, 784 Fluorine An Oxido of, P Lebeau and A Damiens, 672;

(F I), The Spectrum of, Prof. H. Dinglo, 938; Oxide of, or Fluoride of Oxygen? Prof. B Brauner, 842
Flying Fox Pest in Australia, The, Prof. A. C. D. Rivett,

Fog Production on the Neutralisation of Halogen Halides. H. O. Askew, 275

d Investigation Board, Report of the, 1925, 1926, 675, Poisoning, Dr. W G Savage, 629

Foraminifera of the Genus Lepidocyclina, Dr T W. Vaughan, 420

Forest and Pranie, Prof H C. Cowles, 931

Foresters, the Society of, of Great Britain, Foundation of, 342 Forestry: No. 1, 342, 386, Commission. Seventh Annual Report, 177, in India, C E Simmons, 251; in Kenya Colony, 899; in Trinidad and Tobago, 748; Research in South Africa, Dr. J. Phillips, 461

Forests: and Floods, 92, The Conservation of, 316 Formaldehyde, Synthetic, W. Ledbury and E. W. Blair,

Forthcoming Books of Science, 532

Fossil: Fishes from the North of Madagascar, Some, J Piveteau, 31; Insocts, Dr. R J Tillyard, 383 Fourier Constants, On. E. T. Copson, 825

Fowls and Ducks, A Thumb Claw in, T. Kageyama, 855

Frankland, Sir Edward, A Relic of, W. F, 226 Frazer lecture in 1928, Prof. E. Westermarck to deliver the, 343

Frequency Demultiplication, Dr. B. van der Pol and J. van der Mark, 363

Fresh-water: Amoba, The Behaviour and the Rôle of the Contractile Vacuole of a, E Wolff, 714; Biology in Norway, Prof. H. H. Gran and Miss Birgithe Rund, 598, Eels in the Pacific Area, Dr. Johs. Schmidt 457 Fresnel, Augustin Jean, Centenary of the death of, 57

Fritz, John, medal, Award of the, to Gen. J. J. Carty, 893 Frunt Canning in the Home, 966; The Storage of, 675; Trees, The Physiology of, Dr. T. Swarbrick, 240

Fuel. Institute of, presidential address to the, Sir Alfred Mond; F Hodgos elected president, 850; Research Board, Report of the, for 1926, 237
Fundulus, Xanthophore Changes m, Nervous Control of, E F. B Fries, 570

Fuse-spectra, Shifts and Reversals in, A. C. Menzies, 901

γ-ray Emission and the Law of Radioactive Transformation, J C Jacobsen, 874 Galaxy, The Rotation of the, Dr. J. H. Oort, 491, 894 Gale's Comet, 419

Gamma Irradiation, The Effect of, on Cell Division in Tissue Culture in vitro, R. G. Canti and F. G. Spear, 65 Gas: Absorption, The Phenomena of, and Equilibrium of Pressure in Lamps without Filament, J. Risler, 861; Analysis, The Calculation of, Brutzkus, 791; Effluents Research Committee, Report of the, 384; Industry, The, and Carbonisation, 63, Studies of, Solid Equilibria, I, B. Lambert and A. M. Clark, 750
Gaseous: Carbon Tetrachloride, The Refraction and Dis-

persion of, H. Lowery, 138; Chemical Reactions, Radiation and Collision in, J. H. Hibben, 571, Com-Madiation and Collision in, J. H. Hibben, 571, Combustion. at High Pressures, Part VIII, Dr. D. T. A. Townend, 748; in Electric Discharges, Part II., G. I. Finch and L. G. Cowen, 748, at High Pressures, Prof. W. A. Bone, 814, Phase in High Frequency Electro-magnetic Fields, Some Chemical Reactions in the, R. Moens and A. Juliard, 643, Phosphoretted Hydrogen, The Sensibility of some Test Papers towards, M. Wilmet, 139

Gases Dissolved in Water, Measurement of the, L. Dunover,

350

- Gasteromycetes of Australasia, The, (9), G. H. Cunningham.
- Gauge-invariant Tensor Calculus, A. M. H. A. Newman, 753 Geissler Discharges, The Positive Column of, Prof. Guntherschulze, 97

Gene, Size of the, Dr. A. S. Serebrovsky, 313

Genetics · International Congress of, Prof. R. R. Gates, 495 , Physiological, Prof. J. S. Huxley, 109 Geneva, Lake of, Two New Alga in the Flora of the,
